ABBREVIATIONS

aq. = aqueous

atm. = atmospheric or atmosphere(s)

at. vol. = atomic volume(s)

at. wt. = atomic weight(s)

$T°$ or $°K$ = absolute degrees of temperature

b.p. = boiling point(s)

$θ°$ = centigrade degrees of temperature

coeff. = coefficient

conc. = concentrated or concentration

dil. = dilute

eq. = equivalent(s)

f.p. = freezing point(s)

m.p. = melting point(s)

$mol(s) = \begin{cases} \text{gram-molecule(s)} \\ \text{gram-molecular} \end{cases}$

$mol(s). = \begin{cases} \text{molecule(s)} \\ \text{molecular} \end{cases}$

mol. ht. = molecular heat(s)

mol. vol. = molecular volume(s)

mol. wt. = molecular weight(s)

press. = pressure(s)

sat. = saturated

soln. = solution(s)

sp. gr. = specific gravity (gravities)

sp. ht. = specific heat(s)

sp. vol. = specific volume(s)

temp. = temperature(s)

vap. = vapour

In the **cross references** the first number in clarendon type is the number of the volume ; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus **5**. 38, 24 refers to § 24, chapter 38, volume 5.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements ; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of **triangular diagrams** for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, **49**. 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances A, B, and C, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the

triangle represent the single components *A*, *B*, and *C*, the sides of the triangle represent binary mixtures of *A* and *B*, *B* and *C*, or *C* and *A* ; and points within the triangle ternary mixture. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure *A* will be represented by a point at the apex marked *A*. If 100 be the
FIG. 1.   FIG. 2.   FIG. 3.

standard of reference, the point *A* represents 100 per cent. of *A* and nothing else; mixtures containing 80 per cent. of *A* are represented by a point on the line 88, 60 per cent. of *A* by a point on the line 66, etc. Similarly with *B* and *C*—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig 4 results. Any point in this
FIG. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point *M* represents a mixture containing 20 per cent. of *A*, 20 per cent. of *B*, and 60 per cent. of *C*.

CHAPTER XLI

TITANIUM

§ 1. The Discovery of Titanium

In 1791, W. Gregor [1] studied the black sands of Menacan, near Falmouth, Cornwall, and found some greyish-black granules which were attracted by a magnet. He digested 100 grains of the mineral with hydrochloric acid and obtained an insoluble grey powder, and a soln. which, when treated with aq. ammonia, furnished a precipitate which, on calcination, gave $46\frac{9}{16}$ grains of magnetic oxide of iron with traces of manganese oxide. When the grey powder was digested for a long time with hot sulphuric acid, an insoluble residue was obtained, which, after calcination, contained $3\frac{1}{2}$ grains of silica. When the yellow sulphuric acid soln. was treated with potash-lye, a white precipitate was obtained which gave on calcination 45 grains of a brownish calx. W. Gregor's analysis of the black sand is therefore

Magnetite $46\frac{9}{16}$	Silica. $3\frac{1}{2}$	Brownish calx. 45	Loss. $4\frac{15}{16}$ per cent.

The yellow sulphuric acid soln. was changed to an amethyst or purple colour by the action of metallic zinc, tin, or iron ; and to yellow, by tincture of galls. The precipitate itself, in contact with dil. acid, is also coloured purple by contact with zinc ; and a reddish-purple slag is obtained when an intimate mixture of the powdered mineral and coal-dust is fused in a crucible. Hence, said W. Gregor :

> The extraordinary properties of the sand have led me to believe that it contains a new metallic substance. In order to distinguish this substance from others, I have ventured to suggest a name derived from the neighbourhood—Menacan, Cornwall—where it was found, and therefore I propose to call the metal *menacanite*.

Three years later, M. H. Klaproth [2] analyzed a specimen of a mineral from Boinik, called *Hungarian red schörl*. He found this product to be a natural metallic oxide which possessed peculiar properties, and hence, he inferred it to be the calx of a new metal which he called *titanium*. The name was borrowed from mythology —the Titans, " the first sons of the earth "—because, " in order to avoid giving rise to erroneous ideas, it is best to choose a name which means nothing in itself, whenever no name can be found which indicates the peculiar and characteristic properties of a substance." About the same time, 1794, M. H. Klaproth also found that a brown mineral from Passau contained about 33 per cent. of titanium oxide, 33 per cent. of lime, and 33 per cent. of silica, with a trace of manganese. He called this mineral *titanite*. About 1797, the same observer analyzed the black magnetic sand from Menacan, and found it to contain iron oxide, 51 per cent. ; titanium oxide, 42·25 per cent. ; silica, 3·5 per cent. ; and manganese oxide, 0·25 per cent. He accordingly suggested that the suspected new element in W. Gregor's mineral— *kein anderer sei, als eben der, welcher den hungarischen roten Schorl bildet ; namlich Titankalk*, so that W. Gregor's new metallic substance is identical with M. H. Klaproth's titanium. M. H. Klaproth's results were confirmed by W. A. Lampadius,[3] J. T. Lowitz, and L. N. Vauquelin, but the systematic investigation of purified titanic oxide was made by H. Rose, about 1824. The impure metal was isolated by J. J. Berzelius in 1825, and by F. Wöhler, in 1849 ; but it

was not until comparatively recent times that a metal of even a moderate degree of purity was obtained.

A. Scott [4] reported a new element from the black titaniferous sands of Maketu, New Zealand. The properties of its compounds were those characteristic of the titanium-uranium family; its at. wt. was stated to be 144; and it was said to form a cinnamon-coloured oxide very resistant to chemical agents. He proposed calling the new element *oceanium*—from Oceanus, one of the Titans. D. Coster and G. Hevesy's examination of A. Scott's preparation showed no X-ray spectral lines characteristic of a new element; and C. J. Smithells and F. S. Goucher failed to establish the existence of a new element in the Maketu sands. A. Scott showed later that the oxide of the supposed new element was nothing more than titanium oxide associated with silica, and postulated that part of the titanium was replaced by silicon. The colour was due to the presence of a little iron oxide.

§ 2. The Occurrence of Titanium

The metal does not occur free in nature. Its compounds are very widely diffused in small quantities; indeed, although titanium is often grouped with the scarce metals, it appears to be more abundant than copper, lead, zinc, or any of the common metals except iron. Titanium, however, is rarely found with any considerable quantity located in one spot. Concentrated deposits are scarce. Titanium is nearly always a constituent of igneous rocks, and of sediments derived therefrom. According to F. W. Clarke,[1] out of 800 rocks analyzed in the United States, 784 contained titanium. J. H. L. Vogt, J. F. Kemp, A. Harker, and H. S. Washington also made confirmatory reports. From J. Joly's and F. W. Clarke's estimates 0·46 per cent. of the earth's crust is titanium, 27·7 per cent. silicon, and thorium 0·002 per cent. F. W. Clarke and H. S. Washington gave 0·46 per cent. of titanium; and J. H. L. Vogt, 0·33 per cent. According to A. J. Angström,[2] F. Cornu, G. Salet, R. Thalén, H. L. Cortie, J. N. Lockyer and F. E. Baxandall, H. Deslandres, W. M. Mitchell, M. N. Saha, F. W. Dyson, and W. S. Adams, titanium is present, probably in the gaseous state, in the atm. of the sun. A. Fowler observed it in the spectra of stars. A. Daubrée, C. F. Rammelsberg, G. P. Merrill and H. N. Stokes, and E. E. Howell and co-workers found titanium in various meteorites.

The most important mineral sources of titanium are rutile and ilmenite; perowskite and sphene are of less importance. These minerals are discussed elsewhere. **Rutile** contains 90–100 per cent. TiO_2 (*q.v.*), and varieties are represented by the minerals *crispite, davidite, dicksbergite, ilmenorutile, nigrine, sagenite*, and *strüverite*. Another tetragonal form of rutile is **anatase** or *octahedrite;* and the rhombic form is **brookite,** with its varieties *arkansite* and *jurinite*. The **titanates** are represented by **ilmenite,** a ferrous titanate, $FeTiO_3$. This mineral has 3 to 59 per cent. TiO_2, and varieties are called *crichtonite, hystatite, iserine, kibdelophane, picroilmenite, titanoferrite, washingtonite*, and *titaniferous iron ore*. The ferric orthotitanate, $Fe_4(TiO_4)_3$, is represented by **pseudobrookite,** and ferric meta-titanate, $Fe_2(TiO_3)_3$, by **arizonite;** calcium metatitanate, $CaTiO_3$, by **perowskite;**

hydrotitanite is an altered perowskite ; and *knopite* is a related variety. Magnesium metatitanate, $MgTiO_3$, is represented by **geikielite ;** manganese metatitanate, $MnTiO_3$, by **pyrophanite ;** a mixed mesodititanate $(Fe,Mn,Pb)TiO_3$, by *senaite*. *Astrophyllite* is a titanium silicate ; and *lamprophyllite* is a related variety. The **titanosilicates** are represented by **sphene** or *titanite*, $CaTiSiO_5$, and *guarinite*, $CaTiSiO_1$. As varieties appear *alshedite, aspidelite, eucolite-titanite, greenovite, grothite, lederite, ligurite, menacanite, pictite, spinthere ;* and *yttrotitanite ;* with the alteration products *leucoxene, titanomorphite,* and *xanthitane.* A barium titanosilicate, $BaTiSi_3O_9$, is represented by *benitoite.* A titaniferous garnet is called *schlorlomite,* and the variety *ivaarite ; œnigmatite* and the variety *cossyrite* are iron and columbium titanosilicates ; *neptunite* is a titanosilicate of alkalies and iron ; *keilhauite,* of calcium, aluminium, iron, and yttrium ; *narsarsukite,* iron and sodium ; *lorenzenite,* of sodium and zirconium ; *leucosphenite,* sodium, barium, and zirconium ; *tscheffkinite,* of calcium, iron, aluminium, cerium, and yttrium ; and *molengraaffite* and *rhonite* are still more complex. The **borotitanates** are represented by *warwickite ;* and the **titanoantimonites** by *lewisite, mauzelite,* and *derbylite—vide* antimonites.

J. C. G. de Marignac [3] showed that a number of columbates and tantalates may be regarded as titanium minerals, although they are separately discussed with the elements columbium and tantalum. For example, *æschynite* (21 per cent. TiO_2), *blomstrandine* (21–23 per cent. TiO_2), *blomstrandite* (10–11 per cent. TiO_2), *chalcolamprite* are related to *pyrochlore, dysanalyte* (40–60 per cent. TiO_2), *epistolite* (7–8 per cent. TiO_2), *euxenite* (20–24 per cent. TiO_2), *marignacite* and *pyrochlore* (5·14 per cent. TiO_2), *polycrase* (25–30 per cent. TiO_2), *polymignite* (18–19 per cent. TiO_2), *risörite* (6–7 per cent. TiO_2), and *wilkite* (23–24 per cent. TiO_2). Similar remarks apply to the cerium minerals *johnstrupite* (7–8 per cent. TiO_2), *mosandrite* (5–10 per cent. TiO_2), *rinkite* (13–14 per cent. TiO_2) ; the yttrium minerals *delorenzite* (55–70 per cent. TiO_2), and *yttrocrasite* (40–50 per cent. TiO_2) ; and the zirconium minerals *hainite* (28–32 per cent. TiO_2), *rosenbuschite* (20 per cent. TiO_2), and *zirkelite* (14–15 per cent. TiO_2). The occurrence of titanium in the spinel *hoegbomite* was discussed by T. L. Watson.[4] Many observations,[5] in addition to those cited above, have been made on the occurrence of titanium in minerals.

E. Cohen,[6] M. F. Heddle, E. Jackson, P. Jannasch and J. H. Kloos, F. Knapp, E. Riley, H. Rose, A. Sauer, T. Scheerer, A. Stelzner, G. Vogt, and L. van Werweke have emphasized the almost ubiquitous occurrence of titanium in silicate rocks. R. Apjohn, and V. Roussel found it in basalt and trap rocks. A. F. de Fourcroy and L. N. Vauquelin found titanium in the ferruginous gangue of the platinum deposits ; and A. Damour, J. J. Berzelius and co-workers, and A. des Cloizeaux, in auriferous and platiniferous sands. T. Thomson, and R. D. Silva reported it in various sands ; H. St. C. Deville, in bauxite ; and J. Peschier, H. Rose, and L. N. Vauquelin, in many micas. L. Dieulafait reported it in various primordial rocks ; and A. B. Griffiths found 0·68 per cent. TiO_2 in the volcanic ash of Mt. Pelée ; and P. A. Dufrénoy, in volcanic iron. It occurs in biotite (up to 5 per cent.), lepidomelane (up to 5 per cent.), titanolivine (up to 6 per cent.), pyroxenes (up to 5 per cent.), andradite (up to 10 per cent.), and in amphiboles (up to 9 per cent.). It has been found in felspars, dolomitic marble, nepheline, etc. Analyses have been reported by F. P. Dunnington, W. P. Jorissen, A. Harker, F. W. Clarke, H. S. Washington, W. M. Thornton, etc. It is a very common constituent of clays, and was noted in various clays by C. M. Kersten, W. F. Salm-Horstmar, E. Riley, G. Vogt, C. Bischof, W. Aleksiejeff, F. P. Dunnington, etc. R. H. Brett and G. Bird found titanium in Hessian crucibles, but F. Wöhler and A. Schwarzenberg, O. L. Erdmann, and J. E. Herberger could not confirm this. Titanium was found in most soils examined by W. F. Salm-Horstmar, E. Jackson, F. P. Dunnington, G. F. McCaleb, E. Odernheimer, etc. W. O. Robinson and W. J. McCaughey found it in the soils of Chinese tea plantations. W. Biltz and

E. Marcus detected it in the clay of the Stassfurt salt beds. C. Baskerville found it in peat ; E. Jackson, in coal ash ; C. E. Wait, in bituminous coal (0·69–0·95 per cent.), and anthracite (up to 2·59 per cent.). L. Franck found some diamonds coloured with titanium ; but H. Moissan did not find any in the ash of diamonds. This element is found in beds of hæmatite and magnetite, forming titaniferous magnetites. J. T. Singewald,[7] C. U. Slocum, A. Vogel and C. Reischauer, etc., have discussed this subject. The occurrence of titanium in iron ores has been reported by A. Terreil, J. H. L. Vogt, E. Riley, H. Rose, R. Mushet, J. J. Nöggerath, T. Virlet d'Aoust, C. F. Rammelsberg, R. Thalén, G. W. Maynard, R. Akerman, E. J. Chapman, P. W. Shimer, A. Tamm, T. König and O. F. von der Pfordten, T. W. Hogg, A. Ledebur, J. F. Kemp, T. H. Cope, L. de Launey, N. P. Hulst, F. W. Clarke, P. Berthier, H. S. Washington, H. le Chatelier, etc. P. C. Grignon, and W. H. Wollaston found crystals of titanium, or rather titanium carbonitride, in the iron slags of Merthyr Tydvil, Wales ; and they have been remarked by many others—C. Reinhardt, E. Franck, J. J. Nöggerath, B. Osann, H. von Fehling, M. Meyer, F. L. Hünefeld, T. W. Hogg, J. W. Döbereiner, G. F. Comstock, C. M. Kersten, etc. The crystals have also been observed in blast-furnace iron by F. A. Walchner, H. E. F. G. Sandberger, E. Emmons and W. R. Johnson, J. K. L. Zincken, A. Laugier, R. Akerman, C. F. B. Karsten, J. Nöggerath, L. Franck, J. L. Bell, H. Blumenau, H. D. Rogers, W. H. Harris and J. Stenson, J. Percy, B. Kerl, A. J. Rossi, C. F. Rammelsberg, D. Forbes, T. S. Hunt, G. W. Maynard, C. U. Slocum, J. Hörnhager, F. Kick and W. F. Gintl, W. Bettel, and E. Riley ; and described in various treatises on the manufacture of iron and steel. The element has been reported in various iron alloys and in steel, by A. J. Rossi and co-workers, J. A. Paris, R. Mushet, E. Riley, O. Bauer, E. Bahlsen, J. H. Pratt, R. A. Hadfield, L. Guillet, C. U. Slocum, W. Venator, F. A. Fitzgerald, L. Treuheit, E. von Maltitz, P. H. Dudley, G. B. Waterhouse, A. E. Nordenskjöld, E. L. Gruner, A. Nies, A. Carnot and E. Goutal, etc. C. H. Pfaff reported titanium in a sample of commercial sulphuric acid. M. Mazade, and O. Henry found titanium in the mineral water of Nérac. E. Jackson, and C. E. Wait found this element in the ashes of many plants—the former found it in cotton-seed cake, sawdust, and in the seeds of French beans ; the latter found apple- and pear-tree ash contained 0·21 per cent. TiO_2 ; oak-wood ash, 0·31 per cent. ; apples, 0·11 per cent. ; cow-peas ash, 0·01 per cent. ; cotton-seed cake, 0·02 per cent. ; and F. Traetta-Mosca found it spectroscopically in tobacco. E. O. von Lippmann found 0·12 per cent. of titanium in vinasse. G. O. Rees found titanium in human blood and in the suprarenal glands, but R. L. Marchand contradicted this ; however, C. Baskerville found 0·0195 per cent. titanium in beef-bone ; 0·013 per cent. in beef flesh ; 0·0325 per cent. in human flesh ; and a trace in human bone.

§ 3. The Extraction of Titania

In an old process used by H. Rose [1] for extracting titanium dioxide or titania from rutile or titaniferous iron-ore, the mineral was heated to redness in a stream of hydrogen sulphide, and the iron sulphide removed by extraction with conc. hydrochloric acid, and the hydrated titania well washed. To remove all the iron, a repetition of the process is necessary. He also converted the iron into soluble sulphide by fusing the powdered mineral with sulphur, extracted the mass with hydrochloric acid, and treated the washed product with hydrogen sulphide as just indicated. H. Rose extracted rutile or titaniferous iron ore with hydrochloric acid and fused it with over three times its weight of potassium carbonate, or better, according to A. Laugier, with twice its weight of potassium hydroxide. The cold mass was washed with water until the acid potassium titanate began to pass through the filter-paper. The washed residue contained ferric oxide and potassium titanate. C. Friedel and J. Guérin volatilized the iron as chloride by heating the mixed precipitate in a current of hydrogen chloride and chlorine. To obtain titanium dioxide of a very high degree of purity, A. Stähler, and O. F. von der Pfordten recommended converting the oxide to the chloride—*vide infra;* treating the aq. soln. with ammonia; and igniting the washed precipitate.

There are many ways of separating the iron and titanium oxides from the soln. of the residue in cold conc. hydrochloric acid. If this soln. be boiled, the titanium chloride is hydrolyzed and titanium hydroxide is precipitated. According to H. Rose, the hydrolysis is facilitated by the addition of sulphuric acid—*vide infra*, action of sulphuric acid on titanium dioxide. The precipitate is still contaminated with iron. If, however, the iron be reduced to the ferrous condition before the hydrolysis, it will not be precipitated with the titanium. P. Berthier recommended sulphur dioxide or ammonium sulphide

as a reducing agent; V. Merz, and O. F. von der Pfordten, hydrogen sulphide; and F. Stromeyer, sodium thiosulphate. H. Rose treated the soln. with ammonia, and digested the precipitate with ammonium sulphide to convert the iron and manganese oxides into the bivalent sulphides, which were removed by hydrochloric acid. H. Rose also found that the iron can be kept in soln. by adding enough tartaric acid before the treatment with ammonia. G. Streit and B. Franz recommended acetic acid in place of tartaric, although other organic acids will do as well. A. Laugier, for example, used oxalic acid or ammonium oxalate. C. Dreher applied these principles to extract titanium dioxide from substances (such as bauxite residues) containing titanic acid associated with iron, aluminium, and other metals; the mineral is treated with sulphuric or other acid, and the iron is reduced to the bivalent condition by producing nascent hydrogen in the soln. by electrolysis or other means. The acids are nearly neutralized by an alkaline earth or corresponding carbonate; or substances, such as sulphites, acetates, or formates, may be added to bind the acid employed, without dissolving the titanous oxide which is precipitated.

P. Berthier fused the mineral with a mixture of sodium carbonate and sulphur added in small portions at a time to the hot crucible; and afterwards dissolved the mass in cold dil. sulphuric acid. The soln. was treated with sodium carbonate, the ferrous iron remained in soln., and the titanic acid was precipitated. R. Weber opened the mineral by fusion with twice its weight of fluorspar, and digested the cold mass with dil. sulphuric acid. The liquid was filtered from the calcium sulphate, reduced with sulphur dioxide, and boiled to precipitate the titanic oxide. J. C. G. de Marignac brought the mineral into soln. by fusion with potassium hydrosulphate; the cold cake was dissolved in water; the liquid diluted so that it contained 1 vol. of sulphuric acid to 6 vols. of water; and the soln. boiled to precipitate the titanic oxide. G. W. Sears and L. Quill studied the opening of titanium ores with alkali pyrosulphates, and found the sodium salt to be rather more efficient than the potassium salt. At least 12·5 parts of sodium pyrosulphate should be employed for one part of ore. F. Wöhler fused the finely powdered mineral with three times its weight of potassium carbonate, and digested the powdered cake with dil. hydrofluoric acid. The sparingly soluble potassium fluotitanate was boiled with sufficient water to dissolve all the salt; the soln. filtered while hot; and, on cooling, the potassium fluotitanate was obtained as lustrous, scaly crystals. The salt was washed with cold water, and purified by recrystallization from boiling water. The hot soln. can be treated with ammonia, and the washed precipitate ignited for titanium dioxide of a high degree of purity. V. Merz, and also L. Weiss and H. Kaiser, used a modification of this process. G. Streit and B. Franz found that much titanium dioxide remained in soln. with the ferric salt. F. Erban recommended the following process:

The ore is melted with sodium hydroxide, lixiviated with water, and the residue washed to free it from alkali. The product is dissolved in hydrochloric acid, and the soln. treated with alkali to precipitate the titanium as hydroxide. Iron is removed by adding sodium sulphide, washing the precipitate, and treating it with sulphurous acid. It is then converted into the double oxalate of titanium and ammonium by treatment with oxalic acid and ammonium oxalate. Thirty parts of rutile containing 80–90 per cent. of titanic acid gave 120 parts of "oxalate." The ignited precipitate furnished titanium dioxide.

F. Bayer prepared titanic acid from ferrotitanium by heating the alloy with calcium oxide or carbonate, and extracting the product with acids. P. H. Monk and C. Whittemore, and E. E. and P. C. Dutt discussed the extraction of titanic oxide from bauxites, etc. G. Siebert and E. Korten treated the raw material with halogens in the presence of carbon at a high temp. G. Carteret and M. Devaux described the following process:

The ore is heated in a retort at 800° for 1 or 2 hrs. in the presence of a slow current of reducing gas or mixed with carbon. Dry chlorine is passed through the furnace heated to 350°. At this temp., the iron only is attacked, and the ferric chloride formed passes out and is collected. The direction of the chlorine current is then reversed, and the temp. raised to 550°–600°. The titanium is attacked, and the titanium chloride, contaminated with traces of iron, silicon, etc., passes out through another opening. The titanium chloride is purified by distillation, and may be used for the preparation of titanium sulphate and oxide.

J. Blumenfeld opened the mineral by digestion with sulphuric acid; and J. Blumenfeld and C. Weizmann extracted titanic acid from ilmenite by the following process :

The mineral was heated with sulphuric acid of 70–90 per cent. conc. at 150°–180° for 1½ hrs. or for some time after the mass had become a dry powder. This was cooled to 50°, a limited quantity of water (such that only about 15–20 per cent. of the iron dissolves) added, and the whole stirred with spongy iron to reduce any ferric sulphate. The bulk of the ferrous sulphate remained undissolved and was filtered off. The titanium contained in the filtrate was precipitated as hydroxide and the latter washed with acidified water containing a small quantity of salts of trivalent titanium until free from iron. The hydroxide was calcined under oxidizing conditions, and yielded titanic acid of a colour suitable for use as a white pigment. T. Matsubaka said that the calcining temp. should not exceed 400°, and that an excess of acid reduces the yield of titanic oxide.

§ 4. The Preparation of Titanium

In 1825, J. J. Berzelius [1] prepared what he called *amorphes Titan* by reducing potassium fluotitanate, K_2TiF_6, with sodium ; the black powder gave metallic streaks when rubbed with a polishing tool, and it was said to be " insoluble in hydrofluoric acid," whereas it is now known that the element readily dissolves in that menstruum. When M. A. Hunter repeated J. J. Berzelius' experiment, in vacuo, his best product contained but 73·2 per cent. of titanium. W. A. Lampadius [2] then heated a mixture of titaniferous earth and carbon in a clay crucible and obtained a dark brown metal which detonated when mixed with saltpetre and heated. A. Laugier likewise heated a mixture of the earth with oil, and obtained yellow crystals resembling some curious crystals found in blast-furnace slags—*Hochöfenkrystallen*. As indicated above, W. H. Wollaston mistook these crystals for the crystalline form of the metal itself. F. Wöhler isolated the impure metal in 1849, and showed that the product obtained by the high temp. reduction of the oxide by carbon was not the metal, but rather a mixture of the nitride and carbide—titanium carbonitride or cyanide. Thus, by heating W. H. Wollaston's " metal " in chlorine gas, F. Wöhler showed that it contained :

	Titanium.	Nitrogen.	Carbon.
W. H. Wollaston's product	77·26	18·30	4·56
Calculated for $Ti_{10}C_3N_8$	78·00	18·11	3·89

On account of the high m.p. of the metal, and the ease with which it unites with oxygen, carbon, nitrogen, silicon, and the other elements, it is doubtful if anything but a very impure form of the metal was really obtained by J. J. Berzelius, and F. Wöhler. The metallic appearance of the titanium nitrides also led to their being confused with the metal. Thus, H. Rose's dark blue or black powder obtained by heating titanium tetramminotetrachloride, $TiCl_4.4NH_3$, alone or with sodium, is now known to be a nitride. Accordingly, the early reports of the isolation of the metal are quite unreliable, and many early records of the properties of titanium are confused, and contradictory, and therefore erroneous.

(1) *Reduction of the halogen salts with the alkali metals.*—J. J. Berzelius,[3] and F. Wöhler reduced potassium fluotitanate with potassium or sodium, with or without a layer of sodium chloride above to protect the mass from oxidation; but A. Schüller and V. Wartha showed that the product always contained a relatively large proportion of titanium nitride; E. A. Schneider, oxygen and hydrogen; and V. Merz, that it contained sodium, and that in removing the alkali fluorides by washing with water, the latter reacts with the finely-divided titanium, forming titanium oxide. F. Wöhler and H. St. C. Deville heated a boat of the alkali fluotitanate and a boat of sodium in a stream of hydrogen, when the vapour of sodium passing over the fluotitanate effected the reduction. The metal was obtained by washing the product. E. Glatzel used a similar process. Instead of using glass or porcelain, L. Lévy said that enamelled iron can be employed as the containing vessel. He also used a copper vessel. V. Merz tried to obtain the titanium in a crystalline state by adding zinc to the mixture, but the results were nugatory. The product obtained by H. St. C. Deville must have contained carbonitride. V. Merz, and A. Polis tried to obtain the amorphous titanium in a crystalline state by addition of zinc, but the results were not satisfactory.

In 1876, S. Kern[4] passed the vapour of titanium tetrachloride over molten sodium and obtained a product resembling J. J. Berzelius' amorphous titanium, contaminated, according to L. F. Nilson and O. Pettersson, with oxygen; and, according to C. Winkler, with titanium monoxide. F. C. Robinson and C. C. Hutchins said that the reaction commences at about 150°, but O. F. von der Pfordten could not confirm this. M. Billy claimed to have made 100 per cent. titanium by the action of the vapour of purified titanium tetrachloride on sodium hydride at 400°; the product is heated to 400° in a stream of carbon dioxide, and then to 800° to decompose any solid titanium hydride which is produced simultaneously. L. F. Nilson and O. Pettersson reduced the tetrachloride by heating it in an air-tight steel bomb at a red heat, but the results were disappointing because the yellow scales so obtained only contained 94·73 per cent. of titanium; the chief impurity, oxygen, was probably combined as titanium monoxide, TiO_2, and, if so, the product could have contained only 78·97 per cent. of free titanium. In fact, all the specimens obtained by the above process were contaminated with much oxide which may have been produced by the action of water during the leaching of the product of the reaction from the amorphous metal. M. A. Hunter, however, heated a mixture of highly purified titanium tetrachloride and sodium in a steel bomb capable of withstanding an internal press. of 40,000 kilograms. The temp. was raised to a dull red heat so as to start the reaction, which was over in a few moments. On leaching the product with water, a grey powder, mixed with small, rounded grains of the fused metal, was obtained. The fused metal contained 99·9 per cent. of titanium, and there was a 71 per cent. yield. E. Podszus obtained 99·7 per cent. titanium by heating sodium and titanium tetrachloride in a steel bomb sealed with lead. M. A. Hunter and A. Jones studied the reaction. A. E. van Arkel and H. de Boer made the metal by passing the vapour of the tetraiodide over a heated tungsten filament. L. Weiss and H. Kaiser purified the metal obtained by reducing the fluotitanate with sodium or aluminium by pressing the mixture into pencils and using the pencils as electrodes in a vacuum arc-furnace.

The arc-furnace employed by L. Weiss and E. Neumann is illustrated by Fig. 1. The mixture of potassium fluotitanate and aluminium was squeezed into rods or pencils 0.4 cm. long, 1.0 cm. broad, and 0.5 cm. thick. These were used as electrodes in an arc-furnace, Fig. 1, which enabled them to be heated in vacuo or in an atm. of any desired gas under reduced press. As in W. von Bolton's furnace the electrode holders were cooled by a current of cold water. The walls of the furnace were also cooled in a similar way. The distance of the electrodes apart was regulated by a rack-and-pinion arrangement. The window in the furnace enabled the arc to be kept in view during the experiment. The lower electrode, the negative pole, was insulated-from the upper vessel. The rods conduct electricity well, and when the electrodes were about 2 or 3 mm. apart, with a current between 60 and 70 amps., at 20 to 25 volts, globules or stalagmites of titanium metal were formed about the lower electrode. The m.p. of the metal is so high that the chief impurity—aluminium—is volatilized. J. W. Marden and M. N. Rich have described other suitable furnaces. The metal separated in fused globules near the ends of the electrodes, and these were detached when the apparatus had cooled.
Fig. 1.—L. Weiss and E. Neumann's Vacuum Arc-Furnace.

(2) *Reduction of the halogen salts or the oxide by calcium, magnesium, or aluminium.*—W. Huppertz,[5] and A. Burger heated a mixture of calcium and titania in a porcelain tube evacuated at about 600°, and raised the temp. to 1050°. The titanium was isolated by washing with a soln. of ammonium chloride, and drying at 100°. The process was recommended by H. Kuzel and E. Wedekind. C. Winkler, and E. A. Schneider showed that the product obtained by the action of magnesium on titanic oxide largely consists of titanium monoxide. It is, however, probable that the reduction proceeds further than the monoxide since magnesium reduces both silica and zirconia to their elements. O. Ruff and H. Brintzinger obtained 82.8 per cent. titanium by reducing titanium dioxide with a sodium-calcium alloy. In H. Goldschmidt's process,[6] titanic oxide is mixed with aluminium, and the mixture ignited with a suitable fuse, when the reaction $3TiO_2+4Al=3Ti+2Al_2O_3$ occurs. The product is contaminated with 5 or 6 per cent. of aluminium which readily alloys with titanium. A. Stavenhagen and E. Schuchard obtained unsatisfactory results. The reaction was studied by W. Huppertz, W. Prandtl and B. Blayer, etc. According to K. A. Kühne, the reaction proceeds more quickly and at a higher temp. if barium or sodium peroxide, or potassium chlorate or perchlorate, is mixed with the initial products : $TiO_2+2Al+BaO_2=BaO+Al_2O_3+Ti$. The consumption of aluminium is, however, augmented.

(3) *Reduction of the oxide by carbon.*—The early attempts by W. A. Lampadius,[7] L. N. Vauquelin, A. Laugier, and P. Berthier to reduce titanium oxide by carbon in a metallurgical furnace yielded a product consisting largely of the nitride. T. S. Hunt, L. Burgess, and E. H. and A. H. Cowles and C. F. Mabery attempted to make titanium by heating a mixture of rutile or titaniferous iron ore and coarsely granular carbon in an electric furnace. In 1895, H. Moissan obtained a sample contaminated with about 5 per cent. of carbon, by heating a mixture of titanic oxide and carbon in an electric arc furnace. The uppermost layer contained the metal or the carbide, the middle layer was crystalline nitride, and the lowest layer was largely contaminated with oxide. By fusing the top layer with an excess of titanic oxide, the proportion of carbon was reduced from 1.91 to 3.81 per cent., and the product was free from nitride and silicon, but it contained some oxide. The carbon was probably present as graphite. The metal was very brittle and possessed a brilliant white fracture. A few years later, H. Moissan distilled titanium in an electric furnace, and condensed the distillate in small crystals. M. A. Hunter heated an intimate mixture of powdered titanic oxide with lamp-

black in vacuo in an Asem electric furnace, and the best results were obtained with a tungsten crucible at 2400°, but even then the product was largely contaminated with oxide and carbide. A. Sternberg and A. Deutsch also patented the preparation of titanium by heating alkali or alkaline earth titanates with carbon between 1000° and 1400°.

(4) *Reduction of the oxide or halogen salts by other reducing agents.*—In attempts by B. Neumann [8] to reduce rutile with silicon, the product contained 2·99 per cent. of iron and 20·37 per cent. of silicon, but no nitrogen. L. Lévy said that he prepared pure crystalline titanium by the action of the vapour of titanium tetrachloride on boron or silicon, but the product was later shown to be a boride or silicide; D. Gardner and L. Taverner used calcium silicide, ferrosilicon, or other silicide as reducing agent. According to E. Wehrlin and E. Giraud, titanium oxide can be reduced to the metal by heating potassium fluotitanate with metallic iron at a bright red heat and removing the iron by treating the cold mass with hydrochloric acid—but this is doubtful. F. Auer prepared titanium by reducing the oxide at a white heat by a mixture of hydrogen and ammonia gases; and J. Schilling reduced ammonium titanate in an atm. of hydrogen or nitrogen. J. J. Ebelmen reduced titanium chloride with hydrogen. L. Lévy said that titanium tetrachloride can be advantageously reduced by mercury ethide in an atm. of carbon dioxide at 180°. Titanium di-iodide, TiI_2, at a bright red-heat, was found by E. Defacqz and H. Copaux to be reduced to amorphous titanium by hydrogen. A. Stahler and F. Bachran found that there is a kind of autoreduction of titanium dichloride when it is heated in a current of hydrogen at 1100°: $2TiCl_2 \rightleftharpoons TiCl_4 + Ti$. H. Fischvoigt and F. Koref obtained ductile titanium by passing the vapour of hydrogen and titanium tetrahalide over a heated tungsten filament. A. E. van Arkel and J. H. de Boer proceeded as follows: The filament is fitted by thicker tungsten electrodes into a glass globe. The tetraiodide is introduced, and the filament brought to incandescence. The whole globe is heated so as to vaporize the iodide and a layer of titanium is deposited on the filament as a lustrous coherent coating. In a few hours rods 2 to 4 mm. thick can be obtained. When the rod is over 3 mm. thick, the current heating the filament rises from 0·5 to 100 amps. The fine core of tungsten now remains as a negligibly small impurity.

(5) *The electrodeposition of titanium.*—J. de Bussy [9] claimed to have obtained silver-white titanium with a bright metallic lustre by the electrolysis of a soln. of potassium titanate, sodium sulphate, and sulphuric acid, but the claim is doubtful. A. C. Becquerel also electrolyzed a conc. hydrochloric acid soln. of titanium and iron chlorides with platinum electrodes; the metal obtained was possibly an iron-titanium alloy, since no deposit is obtained if the iron chloride be excluded. W. Borchers and W. Huppertz electrolyzed molten calcium chloride in which titanic oxide was suspended. The calcium reduced the titanic oxide to titanium, which was separated in the form of a black powder by leaching away the soluble salts with water and hydrochloric acid. J. Königsberger and J. Schilling also obtained compact titanium by electrolyzing molten rutile with carbon electrodes; and H. List, by electrolyzing soln. of rutile in molten potassium chloride.

The **smelting of titaniferous magnetites** in the blast furnace has not been satisfactorily solved. Some difficulties are encountered. These are discussed by B. J. Harrington,[10] D. Forbes, W. M. Bowron, J. T. Singewald, etc. If titaniferous iron ores be treated in a blast furnace in the ordinary way, for instance, the slag is viscid and does not run well; the fuel consumption is high; and titanium nitride and carbonitride form aggregations in the furnace. A. J. Rossi has claimed that the objections owing to the infusibility of the slags do not hold if the ores with up to about 50 per cent. titanium dioxide be properly fluxed. According to G. Gin, and A. Stansfield, direct smelting of the ore in electric furnaces has given very promising results. Two types of ferro-titanium are used as master-alloys in iron and steel metallurgy—*ferro-carbon-titanium* and *ferro-titanium*. In

A. J. Rossi's process for ferro-titanium, almost carbon-free aluminium is first melted in an electric furnace, pig or scrap-iron is then added to the charge, and rutile is introduced; the temp. is then raised to the point necessary to start the reduction of the rutile by the aluminium. The reduced rutile alloys with the iron, and the practical product is carbon-free. Alloys with from 10 to 75 per cent. of titanium and 0·12 to 0·75 per cent. of carbon have been made in this way. With ilmenite or titaniferous iron ore in place of rutile, the consumption of aluminium is increased because it is then used in reducing the ferric oxide contained in these minerals. The alloy is also made by H. Goldschmidt's thermite process. When the alloy is made by reduction with carbon in an electric furnace the product contains 5 to 9 per cent. of carbon mainly in the form of graphite. In order to keep down the losses through the volatilization of titanium, A. J. Rossi used lime along with the furnace charge: $TiO_2 + CaO + 5C = Ti + CaC_2 + 3CO$. Analyses by R. J. Anderson of commercial alloys are:

	Si	Ti	C	Mn	Al	P	S
Ferro-carbon-titanium . .	1·41	15·79	7·46	0·11	0·80	0·05	0·08
Ferro-titanium (Goldschmidt) .	1·0–1·5	25	nil	nil	5·0–6·0	0·05	0·01

A. Sinding-Larsen's process is as follows:

The crushed and dressed ore is heated, in a horizontal revolving retort, to a temp. below that of fusion, and then reduced by some such agent as hydrogen, volatile hydrocarbons or carbon monoxide. As the reduction proceeds, the spongy product, containing the whole of its iron and a portion of its titanium as metal, is passed into a second retort which is heated to about 130°. It is there exposed to a current of carbon monoxide; the iron carbonyl which is formed is conducted to decomposition chambers and decomposed at a temp. of 200° or more, the carbon monoxide being passed back into the second retort. In this way, by suitably shaping the decomposition chambers, it is possible to obtain mouldings of any form, which, however, must subsequently be carbonized since the deposited metal is too pure for technical purposes. The residue in the second retort, consisting of titanium oxide and a certain proportion of titanium, may be heated to a high temperature by means of an electric furnace, subjected to the action of reducing gases, and finally treated with nitrogen, the nitrides obtained being employed as a manure after any unreduced oxides, such as vanadium oxide, have been extracted by means of chlorine or acid.

The variable reports of the effects produced by the addition of titanium to iron and steel possibly depend on whether the titanium is present as a metal alloy or as nitride. Alloys with from 20 to 75 per cent. of silicon and 5 to 70 per cent. of titanium, are called *silico-titanium*, and they are made by reducing a mixture of rutile or titanium dioxide, sand, and carbon in an electric arc-furnace; *ferro-silico-titanium* is made by adding scrap-iron and a certain amount of hæmatite to the charge. *Cupro-silico-titanium* is made by adding copper to the furnace charge. *Cupro-titanium* is manufactured by A. J. Rossi's process with copper in place of iron in the bath of aluminium; and *mangano-titanium* is made by H. Goldschmidt's process with 30 to 35 per cent. of titanium.

§ 5. The Physical Properties of Titanium

The titanium prepared by J. J. Berzelius,[1] and F. Wöhler was impure, and in the form of a grey powder having the appearance of iron reduced by hydrogen at a low temp. The powder acquires a metallic lustre under the burnishing tool. Analyses of titanium were quoted by H. Rose, E. A. Schneider, M. A. Hunter, H. Moissan, and L. Weiss and H. Kaiser. H. Kuzel prepared **colloidal titanium** by the process indicated in connection with colloidal silicon. The **crystals** of the metal reported by many of the early workers—W. H. Wollaston, F. A. Walchner, J. J. Nöggerath, R. J. Haüy—were those of a nitride (J. von Liebig), or carbonitride (W. H. Wollaston), and not of the element at all. Accordingly, as already indicated, many properties attributed to the element do not refer to titanium, but to the carbonitride. The so-called amorphous variety is produced when the halogen salts or oxide are reduced at a low temp., and possibly represent the colloidal metal. V. Merz, and A. Polis tried to crystallize the amorphous form by melting it with zinc or aluminium, but with no definite result on account of the accumulation of titanium in the slag, and the formation of alloys. When cooled from the molten state, titanium gives a crystalline mass resembling polished steel, and, according to L. Lévy, titanium crystallizes in the cubic system; and, according to J. Königsberger, the crystals are isomorphous with those of silicon and zirconium. L. Lévy's metal was probably titanium silicide. A. W. Hull found that titanium crystallizes in the hexagonal system with the axial ratio $a : c = 1 : 1\cdot59$; the **X-radiogram** by A. W. Hull, and R. A. Patterson corresponds with a close packed hexagonal lattice with unit cell having $a=2\cdot97$ A., and $c=4\cdot72$ A., Fig. 2. Each atom of the centred cube is surrounded by eight others. The subject was discussed by M. L. Huggins, G. Greenwood, and L. Vegard. R. A. Patterson observed no change in the space lattice with titanium which had been dipped in liquid air, or heated to 850°.
Fig. 2.— Space Lattice of Titanium, Zirconium, and Cerium.

The **specific gravity** of amorphous titanium given by K. B. Hofmann varied from 3·4973 to 3·5888, and he believed the latter value to be the more probable. L. Weiss and H. Kaiser gave 3·392 to 3·952 at 19° to 20°. C. J. B. Karsten made observations on the sp. gr. of titanium. M. A. Hunter gave 4·50 for the sp. gr. of crystalline titanium; H. Moissan gave for crystals with 2 per cent. of carbon, 4·87; and L. Weiss and H. Kaiser, for metal with 0·3 per cent. of carbon and 1·56 per cent. of hydrogen, 5·174 at 19°. W. G. Mixter gave 4·49 to 4·51 at 18°. The sp. gr. 5·28, reported by C. M. Kersten, and 5·3 by W. H. Wollaston, refer to the carbonitride. L. Weiss and H. Kaiser gave for the **atomic volume** of the crystalline element, 9·3; and K. B. Hofmann, for the amorphous element, 13·4. W. L. Bragg estimated the **atomic radius** to be 1·40 A. R. Gross also discussed this subject. For the value of b of J. D. van der Waals' equation J. J. van Laar estimated $b_c=0\cdot00180$; and for the valency attraction $\sqrt{A}=35$. According to H. Moissan, the **hardness** of crystalline titanium enables it to scratch quartz and steel, but the metal is so brittle that it can be pulverized in an agate mortar. M. A. Hunter found that although so hard and brittle when cold, titanium at a low red heat may be forged like red-hot iron; ·but attempts to produce wire by passing the heated metal through a draw-plate were not successful. A. E. van Arkel and J. H. de Boer made ductile titanium by their process of preparation.

H. St. C. Deville stated that titanium is so refractory that it can be heated in an alumina crucible at the temp. of the vaporization of platinum without melting; and H. Moissan said that fused titanium is the most refractory body we have as yet prepared in the electric furnace; it is more infusible than vanadium, and leaves far behind such metals as chromium, tungsten, molybdenum, and zirconium. As a matter of fact, said M. A. Hunter, the metal is not by any means as refractory

a substance as was formerly believed, for its **melting point** is comparatively low, being within a hundred degrees of that of platinum. M. A. Hunter gave 1800°–1850° for the m.p.; L. Weiss and H. Kaiser, 2200°–2400°; W. Guertler and M. Pirani, 2000°; and G. K. Burgess and R. G. Waltenberg, 1795° ± 15°. O. Ruff found that titanium with about 5 per cent. of carbon melted at 2700° in an electric vacuum furnace. W. Guertler and M. Pirani adopted 2000° as the best representative value. J. K. L. Zincken, and C. Despretz observed the **volatility** of titanium. H. Moissan distilled the metal in an electric arc furnace, and said that its **boiling point** is very high; L. Weiss and H. Kaiser also volatilized the metal when an arc was struck between titanium electrodes. W. R. Mott estimated the b.p. of titanium to be 3400°; and calculated 2800° from J. J. van Laar's data, and the formula $T_c/T_b = 1·60$, where T_c denotes the absolute critical temp., and T_b the absolute b.p. The **critical temperature** is 4490°, and the **critical pressure** 1130 atm. L. F. Nilson and O. Pettersson gave for the **specific heat** and the **atomic heat** of amorphous titanium containing 94·73 per cent. Ti:

	0°–100°	0°–211°	0°–301·5°	0°–440°
Sp. ht. . . .	0·1125	0·1288	0·1485	0·1620
At. ht. . . .	5·40	6·18	7·13	7·77

J. Dewar gave 0·0205 for the sp. ht. between −253° and −196°. L. Weiss and H. Kaiser gave 0·1394 to 0·1437—mean 0·1418 for the sp. ht. of titanium, and 6·830 for the at. ht. M. A. Hunter gave for the sp. ht. 0·1462 from 0° to 100°; 0·1503 from 0° to 187·5°; 0·1516 from 0° to 254°; and 0·1563 from 0° to 333°. P. Nordmeyer and A. L. Bernoulli found the sp. ht. between −185° and 20° to be 0·0824. G. N. Lewis and co-workers gave 6·5 Cals. per degree for the atomic **entropy** of titanium at 25°; and E. D. Eastman, 6·3 Cals. per degree.

The **refraction equivalent** of titanium for red light as found by A. Schrauf [2] is 0·12782 when that of hydrogen as unit is 0·00405; J. H. Gladstone gave for the **atomic refraction** 24·6, and for the sp. refraction, 0·510. C. P. Smyth discussed the relation between the refraction and the electronic structure. R. Thalén [3] gave a drawing and some measurements of the **spark spectrum** of titanium, and observations were made by R. Capron, W. F. Meggers and co-workers, R. J. Lang, A. de Gramont, B. Hasselberg, E. Haschek, H. Gieseler and W. Grotrian, O. Lohse, N. A. Kent, A. Hagenbach and H. Konen, F. Exner and E. Haschek, H. Konen and H. Finger, E. Carter, H. Kayser, C. Keller, A. M. Kilby, F. L. Brown, J. H. Pollok, P. Fiebig, and J. M. Eder and E. Valenta. The more intense lines have the wave-lengths: 2516·10, 3349·20*, 3361·40*, 3372·92*, 3383·87, 3505·10, 3510·99, 3685·37*, 3759·40*, 3761·5*, 3900·81, 3913·72, 4163·90, 4395·20, 4549·90, 4572·27. The six marked with an asterisk were shown by J. H. Pollok to be the most persistent. The **arc spectrum** of titanium was studied by R. Capron, W. F. Meggers and co-workers, J. N. Lockyer, G. D. Liveing and J. Dewar, R. Thalén, H. A. Rowland, A. Hagenbach and H. Konen, R. E. Loving, E. J. Evans, A. M. Kilby, A. S. King, P. Fiebig, M. A. Catalan, C. C. and H. K. Kiess, H. Crew, K. Behner, J. M. Eder and E. Valenta, and F. Exner and E. Haschek. The more persistent lines have the wave-lengths: 3948·87, 3989·94, 3998·80, 4306·09, 4533·40, 4536·16, 4981·93, 4991·24, 4999·68, 5007·35, 5014·39, 5193·12, 5210·59. C. C. and H. K. Kiess studied the regularities in the arc spectrum of titanium. The **flame spectrum** was studied by J. N. Lockyer; the **band spectrum,** by A. Fowler, G. E. Hale and co-workers, P. Fiebig, and J. M. Eder and E. Valenta; the **series spectrum,** by H. N. Russell, C. C. Kiess and W. F. Meggers, and P. G. Nutting; and the ultra-violet spectrum, by A. S. King, R. J. Lang, and F. Exner and E. Haschek. The *enhanced lines* were investigated by J. N. Lockyer, A. S. King, H. M. Reese, M. Kimura and G. Nakamura, and F. E. Baxandall; the effect of *pressure*, by W. J. Humphreys, A. S. King, and H. G. Gale and W. S. Adams; and the effect of a *magnetic field*—the **Zeeman effect**—by H. D. Babcock, H. M. Reese, J. E. Purvis, and A. S. King. H. Gieseler studied the absorption spectrum of the

vapour at 2000°. The relations between the spectra of carbon, boron, silicon, titanium, and zirconium were studied by L. Troost and P. Hautefeuille. According to J. Formanek, titanium salt soln. have no **absorption spectrum,** but with an alcoholic soln. of alkanna, there is a marked absorption band about 6271, and fainter bands about 5782 and 5350. For the titanium lines in the solar spectrum, *vide* the occurrence of titanium. The high frequency or **X-ray spectrum** was studied by G. Wentzel, H. G. J. Moseley, D. Coster, and E. H. Kurth. B. Walter, A. E. Lindh, M. Levi, F. Hund, V. Dolejsek, H. Fricke, E. Hjalmar, M. Siegbahn, D. M. Bose, K. Chamberlain, O. Stelling, H. H. Robinson, and N. Stensson found, in Angström or 10^{-8} cm. units, for the K-series, $a_2a'=2.74648$; a_1a $=2.74284$; a_3 and $a_4=2.7269$; $\beta_1\beta=2.50874$; and $\beta_2\gamma=2.49367$. N. K. Sur discussed the spectrum of ionized titanium, and estimated the **ionizing potential** to be 13 volts.

W. H. Wollaston's[4] observations on the **electrical conductivity** of titanium really refer to the carbonitride. L. Weiss and H. Kaiser found that the metal is a fair conductor; its sp. **electrical resistance** varied from 0.125 to 0.448 ohm. P. W. Bridgman found that the press. coeff. of the conductivity of titanium is very small; it is probably less than 10 per kgrm.; and probably increases with press. F. Streitz attributed the negative temp. coeff. of the resistance of titanium to the presence of minute cavities which close as the temp. rises. J. Königsberger and J. Schilling showed that the absolute electrical resistance of titanium per c.c. changes from 0.000627 at —191° to a minimum of 0.00276 at 140°; this represents the absolute resistance of what they called a-**titanium.** Above this temp., there are changes possibly represented by the dotted lines, Fig. 3, between 275° and 435°, which are but slowly reversible; and above this temp. there appears to be another allotropic form of titanium called β-**titanium,** the electrical resistance of which rises from 0.000540 at 435° to 0.000815° at 560°. There is then a change to another form called γ-**titanium.** The change from γ to β is so slow that the dotted curve representing the resistance of γ-titanium has been realized down to 0.00109 at 15°. To summarize :
FIG. 3.—The Effect of Temperature on the Electrical Resistance of Titanium.

$$\text{a-Ti} \overset{275°}{\rightleftharpoons} \beta\text{-Ti} \overset{560°}{\rightleftharpoons} \gamma\text{-Ti}$$
These allotropic forms of titanium have no relation with the allotropic forms reported by J. J. Berzelius. His a-titanium was obtained by the action of heat on tetramminotetra- chloride and was probably titanium nitride ; his β-titanium was the ordinary amorphous form. The former readily burns when heated in air, the latter resists the action of heat ; the former is readily attacked by boiling nitric acid and aqua regia, the latter resists the strong acids.

A. Thiel and W. Hammerschmidt found the overvoltage of titanium with $0.1N\text{-}H_2SO_4$ to be 0.570 volt. J. Keyrovsky studied the electrolytic soln. press. F. Fischer and G. Iliovici passed sparks between titanium electrodes under liquid argon, and found scarcely any disintegration of the metal. E. T. Wherry found artificial titanium to be a poor radio-detector. According to M. E. Verdet, the amorphous metal is paramagnetic ; and, according to K. Honda, the **magnetic susceptibility** of the purest titanium available was 3.1×10^{-6} at 18°, and 3.5×10^{-6} at 1100° ; S. Meyer gave 1.9×10^{-6} at ordinary temp. F. C. L. Elsner compared the magnetic properties of titanium with those of iron. I. Tamm, A. Duvillier, P. Weiss and P. Collet, and B. Cabrera studied the relation between the magnetic properties and the electronic structure of the atom.

§ 6. The Chemical Properties of Titanium

The whole of the properties of titanium, said H. Moissan,[1] bring it near to those of the metalloids, and more especially to those of silicon. J. B. van Mons made some observations on the affinity of titanium. E. A. Schneider said that amorphous titanium absorbs a large proportion of **hydrogen,** but it is uncertain whether the gas is merely absorbed, or chemically united with the metal. L. Weiss and H. Kaiser doubt if titanium free from occluded hydrogen has ever been made ; a metal melted in vacuo at 2000° still retained 1·56 per cent. of hydrogen. C. Renz passed chloroform vap. over finely divided, red-hot titanium dioxide, and obtained a colourless gas which furnished titanic acid when passed into water. It was assumed that **titanium hydride** was probably formed. It is, however, possible that very finely divided titanium dioxide was carried along with the gas. T. L. Phipson reported the formation of titanium hydride by the action of magnesium on titanic acid. A. Klauber did not make titanium hydride by the electrolysis of a 50 per cent. soln. of sulphuric acid, using a titanium cathode at 110 to 240 volts, and 0·1 to 4·0 amps. ; but by working with a discharge apparatus at 0·2 to 0·4 amp. and 240 volts, using titanium electrodes, and 0·1 to 0·2N-H_2SO_4, good yields of titanium hydride were obtained. It is said to be a colourless and odourless gas burning in air with a colourless flame like hydrogen, and forming titanium dioxide. The gas deposits titanium when passed through a heated glass tube. It gives a yellow soln. with hydrogen dioxide ; a blue soln. with zinc and hydrochloric acid ; and a reddish-orange colour is produced with a crystal of potassium iodide, and the colour disappears when exposed to ammonia. M. Billy claimed to have made a

solid hydride, Ti_4H_5, as a dull black powder by the action of hydrogen and sodium hydride on titanium tetrachloride.

Titanium is stable in **air** at ordinary temp., and E. A. Schneider observed only a slight increase in weight after keeping the amorphous metal at 100°–120° for 15 hrs.; the increase was eq. to the formation of 0·06 per cent. TiO_2. M. A. Hunter found that titanium ignites in air at about 1200°; and H. Moissan that it burns in **oxygen** at 610° with incandescence, leaving a residue of amorphous titanium dioxide. W. G. Mixter gave for the heat of oxidation 218·4 Cals., while L. Weiss and H. Kaiser gave 97·772 Cals. F. Wöhler said that the brilliant combustion of titanium in air is attended by the formation of nitrogenous titanium dioxide, and when the powdered metal is strewn in the flame brilliant sparks appear. The affinity of oxygen for titanium, said C. Winkler, is very great, and many reducing agents furnish a lower oxide, but not the metal. F. Wöhler said that amorphous titanium begins to react with **water** at 100°, but S. Kern, L. Weiss and H. Kaiser, and E. A. Schneider showed that this action occurs only when the metal is contaminated with sodium. H. V. Regnault showed that titanium decomposes steam at a red heat, and H. Moissan found the reaction with pyrophoric titanium begins at 700°, but the decomposition is continuous until about 800°, when hydrogen is given off and titanium dioxide formed.

O. Ruff and R. Ipsen showed that **fluorine** reacts with warmed titanium, forming the tetrafluoride, and, according to F. Wöhler, **chlorine** does not attack titanium in the cold, but at a higher temp., the reaction is attended with incandescence. H. Moissan said the reaction begins at 350°, and that the tetrachloride is formed. He also found that the reaction with **bromine** begins at about 360°, forming, according to F. B. Duppa, the tetrabromide. The reaction with **iodine** begins at a higher temp. than is the case with bromine, there is no appreciable incandescence, and, according to R. Weber, the tetraiodide is formed. C. Willgerodt said that titanium does not act as *Halogenübertrager* for benzene. V. Merz, and L. Weiss and H. Kaiser found that **hydrofluoric acid** dissolves titanium quickly, forming, according to E. Glatzel, and O. Ruff and R. Ipsen, a soln. of the tetrafluoride; H. Moissan, and L. Weiss and H. Kaiser found that a mixture of nitric and hydrofluoric acids dissolves titanium with violent effervescence, and that the reaction is as energetic as with silicon. V. Merz found that with dry **hydrogen chloride,** titanium forms the tetrachloride. According to H. Moissan, and L. Weiss and H. Kaiser, boiling **hydrochloric acid** attacks titanium slowly with the evolution of hydrogen, and a violet soln. is formed. The nature of the product has been discussed by F. Wöhler, O. F. van der Pfordten, E. Glatzel, and E. A. Schneider— *vide* the titanium chlorides.

L. Lévy said that **sulphur** unites with titanium at a high temp.; and H. Moissan found that the attack is slow at the softening point of glass, and a dark-coloured substance is formed which is not attacked by cold hydrochloric acid, but gives off hydrogen sulphide with boiling conc. acid. For the action of **hydrogen sulphide** and **carbon disulphide,** *vide* the titanium sulphides. According to V. Merz, L. Weiss and H. Kaiser, and H. Moissan, cold dil. **sulphuric acid** readily dissolves titanium with the evolution of hydrogen, but heat is required for the continuous action; hot conc. sulphuric acid oxidizes titanium, forming sulphur dioxide, etc. According to H. Moissan, powdered titanium forms a nitride when heated to 800° in a stream of **nitrogen,** and the reaction is attended with vivid incandescence; according to F. Wöhler and H. St. C. Deville, if carbon is present, some carbonitride is formed. E. A. Schneider investigated the relative affinities of nitrogen for titanium, magnesium, and boron. F. Wöhler, and C. Friedel and J. Guérin also found that the nitride is formed when titanium is heated in a current of **ammonia.** V. Merz, L. Weiss and H. Kaiser, and H. Moissan found that dil. **nitric acid** attacks titanium slowly in the cold, but dissolution is faster with the hot acid. Dissolution is also faster with aqua regia, but the coating of titanic acid which is formed soon stops the reaction. With nitric acid of sp. gr. 1·25, R. Weber found that there is

formed much titanic oxide which does not dissolve.   H. Moissan showed that
titanium reacts with **phosphorus** vap. at about 1000°, forming a dark-coloured
phosphide.   The reaction is only superficial.

According to E. A. Schneider, and H. Moissan, **carbon** reacts with titanium
at a high temp., forming a carbide; carbon also dissolves in molten titanium, form-
ing a carbide, and on cooling, the excess of carbon crystallizes out as graphite.
K. Nischk studied the affinity of titanium for carbon.   V. Merz reported that
cold **acetic acid** dissolves titanium slowly.   L. Lévy found that titanium alone,
or mixed with potassium or sodium, does not react with the **alkyl iodides ;**
and that titanium does not react with **zinc, aluminium, or mercury ethides.**
P. Schützenberger and A. Colson studied the absorption of **silicon** or **silicon nitrides**
by titanium.   According to H. Moissan, silicon unites with titanium in the electric
furnace, forming a silicide which is as hard as the diamond.   E. A. Schneider observed
no reduction when titanium and silica are heated together.   H. Moissan showed
that titanium reacts with **boron,** forming a boride of adamantine hardness.   For
the reactions of titanium with the metals, *vide* the titanides.   E. A. Schneider
found that titanium does not react with **alumina** at a bright red heat.

According to H. Moissan, oxidizing agents readily attack titanium ; fused
potassium nitrate, for instance, attacks it without any apparent evolution of
heat, but if powdered titanium be thrown into **potassium chlorate** at its decom-
position temp., there is a reaction attended by a vivid incandescence.   The fused
alkali carbonates attack titanium in the same way as does a mixture of potassium
nitrate and carbonate.   L. Weiss and H. Kaiser found that when a mixture with
potassium chlorate or nitrate, or **potassium permanganate** is heated, an explosion
ensues.   F. Wöhler found that titanium reacts violently when heated with **cupric
oxide** or **lead oxide** (red-lead).   H. Moissan said that **silver fluoride** is reduced
by powdered titanium at 320° with incandescence.   L. Weiss and H. Kaiser found
that molten **potassium hydrosulphate** dissolves titanium, forming a clear soln.
M. G. Levi and co-workers found titanium dissolves slowly in a soln. of **potassium
persulphate,** and still more slowly in one of **ammonium persulphate.**

The alloys of titanium with other metals have not been well investigated.
E. A. Schneider heated a mixture of cuprous chloride, potassium fluotitanate, and
sodium in an atm. of hydrogen, but failed to obtain a satisfactory alloy ; but by
heating a mixture of potassium fluotitanate and sodium in the presence of strips
of **copper** in an atm. of hydrogen, he found that the surface of the copper became
very hard and was scarcely scratched by steel.   By melting together the hardened
parts, he obtained a hard and brittle **cupro-titanium** with 11·85 per cent. of titanium.
K. Nischk made alloys of copper and titanium..   The manufacture of cupro-titanium
by A. J. Rossi's [2] process has been previously described.   M. A. Hunter and
J. W. Bacon measured the electrical resistance of these alloys.   A. J. Rossi
also made an **argento-titanium** by heating a mixture of silver, titanium dioxide,
silver oxide, and aluminium turnings or carbon.   C. Winkler, and L. Lévy
did not succeed in making a *magnesium titanide ;* nor did L. Lévy make a
zinc titanide.

Aluminium titanides are contained in the regulus obtained when rutile is
reduced by aluminium in the alumino-thermite process.   L. Guillet [3] prepared the
titanides Al_3Ti_2 and Al_4Ti, and obtained mixtures corresponding with Al_2Ti,
Al_3Ti, and Al_4Ti ; but there is as yet no satisfactory evidence as to what the actual
compounds really are.   J. Dewar and J. A. Fleming measured the electrical con-
ductivity of some alumino-titanium alloys.   E. van Erckelens studied the f.p. of
alloys with up to 30 per cent. of titanium corresponding with $TiAl_4$, Fig. 4 ; and
H. Schirmeister, the tensile strength.   F. Wöhler prepared what he assumed,
without analysis, to be an **aluminium ditritatitanide,** Al_3Ti_2, by melting together
a mixture of titanic oxide, cryolite, salt, and aluminium for an hour ; it does not
oxidize readily when heated in air ; it burns to titanium and aluminium chlorides
when heated in chlorine or hydrogen chloride ; it dissolves in hydrochloric acid,

forming a violet soln.; nitric acid vigorously attacks the product. L. Weiss and H. Kaiser, and L. Guillet made some observations on this alloy. W. Manchot and P. Richter prepared a regulus by melting 45·5 grms. of aluminium with 24 grms. of potassium titanofluoride, K_2TiF_6; and the excess of aluminium was removed by a warm normal soln. of sodium hydroxide. Analyses of the crystalline plates agree with **aluminium tritatitanide,** Al_3Ti. W. Manchot and A. Leber extended their study of this compound. The sp. gr. is 5·5; it is very hard and brittle. If it be covered with an acid, and allowed to stand in air, the soln. becomes yellow owing to the formation of hydrogen dioxide, and also of pertitanic acid. Boiling acids or alkali-lye dissolve the alloy rapidly; $\frac{1}{2}N-H_2SO_4$ dissolves. The product is oxidized when heated in air; and when heated with chlorine, the reaction is attended with incandescence. From the proportion of hydrogen evolved when the alloy is treated with acids, it was inferred that the titanium is tervalent, and that the constitution is $Al_3Ti-TiAl_3$. L. Lévy reported that he had prepared **aluminium tetritatitanide,** Al_4Ti, by melting sodium and potassium chloride in a crucible made of rutile and graphite; it was also made by reducing titanium dioxide with aluminium under a layer of molten sodium chloride; and by reducing titanium tetrachloride with aluminium. The product was treated with water and then with dil. acid, and a residue was obtained consisting of lustrous, steel-grey lamellæ, with angles of 90°, very brittle, and good conductors of heat; the sp. gr. at 16° is 3·11. The crystals do not alter in air or nitrogen oxides at the ordinary temp., but tarnish when heated, and burn if heated in oxygen. They are not attacked by vap. of sulphur, selenium, phosphorus, or arsenic, but burn in chlorine or in vap. of iodine or bromine, especially the former. Liquid bromine, however, is without action. Superheated steam and cold fuming nitric acid have no action, but hot nitric acid attacks the crystals slightly. Hydrochloric and sulphuric acids act somewhat in the cold and more readily when heated. The crystals burn when heated in hydrogen chloride, and dissolve readily in aqua regia, but are not dissolved by hydrobromic and hydriodic acids, or by mixtures of these acids with nitric acid. Sulphuric acid and calcium fluoride have little action, and potash only partially dissolves the crystals in the cold, but dissolution is complete on heating, with evolution of hydrogen. The crystals have a composition which agrees with the formula $(Ti:Si)Al_4$, and hence it is probable that they are mixtures of the isomorphous compounds, Al_4Ti, and Al_4Si. If zinc or magnesium is substituted for aluminium, no crystals are obtained. E. van Erckelens showed that the tetritatitanide, Fig. 4, forms neither eutectic nor solid soln. with aluminium, the solidus in the series being a straight line at 657°, the m.p. of aluminium. The liquidus rises very sharply with increase in the titanium content, in a smooth curve to a maximum at 1325° and 30·7 per cent. Ti. The alloy with only 2 per cent. Ti commences to solidify at about 1000°

FIG. 4.—Freezing-point Curves of Aluminium-Titanium Alloys.

with the separation of Al_4Ti, followed by freezing of pure aluminium. The microstructure of the alloys shows needles of very hard Al_4Ti embedded in a soft ground-mass. The effect of up to about 1 per cent. titanium on the tensile properties of aluminium is to increase the ultimate strength; but further additions rapidly to reduce the strength. The hardness, specific electrical resistance, and resistance to corrosion are all increased with increase in the titanium content. The chief value of titanium in aluminium alloys depends on its great affinity for nitrogen and oxygen; for by the removal of these impurities the physical properties of the metal are greatly improved. E. Wedekind made some observations on this alloy. E. A. Schneider made an alloy of copper, aluminium, and zinc by
melting aluminium with titanium dioxide and copper under a layer of molten sodium and potassium chlorides.

H. Moissan [4] found that titanium dissolves fairly quickly in molten **lead,** and also in molten **tin.** A. Stavenhagen and E. Schuchardt also noted that **tungsten** and **molybdenum** can be alloyed with titanium. A. W. Clement described an alloy with **chromium** and iron. They also obtained an alloy with **cobalt.** M. A. Hunter and T. W. Bacon measured the electrical resistance of the alloys of **nickel and** titanium. Alloys of titanium and **iron** were made by F. Wöhler and H. St. C. Deville, and C. J. B. Karsten. M. Faraday and J. Stodart, and J. Percy did not succeed in alloying the two metals. In 1859–1861, R. Mushet obtained a number of patents for the preparation of alloys of iron and steel. H. Moissan found titanium dissolves freely in molten iron; and the alloy with iron, and the so-called ferrotitanium, were studied by A. J. Rossi and co-workers, E. Piwowarsky, F. M. Becket, H. W. Gillet and E. L. Mack, G. K. Burgess and G. W. Quick, R. Akerman, E. W. Hopkins, L. Guillet, etc. The preparation of these alloys has been discussed in connection with the smelting of titaniferous iron ores—*vide supra.* J. Lamont studied the equilibrium diagram of alloys of iron with up to 24 per cent. of titanium. Iron holds 6 per cent. of titanium in solid soln., and there are indications of the existence of iron tritatitanide, Fe_3Ti, Fig. 5. The magnetic properties of iron are lowered in presence of titanium. Brinell's hardness for a 500 kgrms. load was raised from 96 for titanium-free iron to 373 for iron having 8·92 per cent. Ti, and to 484 for iron with 21·50 per cent. Ti. M. Wunder and B. Jeanneret found ferro-titanium gives a clear soln. when treated with hot phosphoric acid of sp. gr. 1·75; any carbon present remains undissolved. The presence of titanium nitride and carbonitride can usually be detected microscopically in ferro-titanium. J. Königsberger and K. Schilling found that titanium begins to alloy with **platinum** at about 400°.

FIG. 5.—Freezing Points of the Iron-Titanium Alloys.

Some reactions of analytical importance.—Soln. of titanium disulphate or of titanium dioxide in hydrochloric acid furnish in the cold a precipitate of orthotitanic acid when treated with **potassium hydroxide,** while hot soln. furnish a precipitate of metatitanic acid; the former is slightly soluble in an excess of the reagent, and rapidly dissolves in mineral acids; the latter dissolves very slowly in these acids. Aq. **ammonia, ammonium sulphide,** and **barium carbonate** likewise precipitate orthotitanic acid from cold soln., and metatitanic acid from hot soln. The **hydrolysis by water,** with boiling soln. containing the minimum quantity of free acid, furnishes a precipitate of metatitanic acid. When the soln. is mixed with an **alkali acetate** and boiled, metatitanic acid is again precipitated; a similar result is obtained with **sodium thiosulphate.** A basic phosphate is precipitated by **sodium phosphate,** and it is soluble in mineral acids but insoluble in acetic acid. If **hydrogen dioxide** be added to a slightly acid soln. of titanium sulphate, the soln. is coloured orange-red, and if but a trace of titanium is present, the colour is yellow. Vanadic acid gives a rather browner coloration under similar conditions. **Reducing agents** like tin or zinc and sulphuric or hydrochloric acid, or sodium amalgam colour the soln. blue or violet. O. F. von der Pfordten [5] summarized the main distinguishing tests for bi-, ter-, and quadri-valent titanium salts in Table I. Reactions with potassium cyanide, sodium nitroprusside, sodium formate, citric acid, and tartaric acid were examined by H. Grossmann. The production of a reddish-brown or yellow colour with **dihydroxymaleic acid** was reported by H. J. H. Fenton; with **salicylic acid,** by W. P. Jorissen; and with **phenols, hydroquinone,** and **alkaloids** like morphine or brucine, by L. Lévy. The coloration with salicylic acid is not produced by salts of cerium, iron, aluminium, beryllium, lanthanum, didymium, thorium, zirconium, chromium, or

silicon. J. H. de Boer found that **alizarinsulphonic acid** gives a violet coloration with titanium salts—*vide* zirconium. I. Bellucci and G. Savoia found that **α-nitroso-β-naphthol** and **β-nitroso-α-naphthol** give coloured complex salts with titanium salts in neutral soln., but not in acid soln. F. Steidler observed that various shades of brown are produced by titanium salts on linen or artificial silk dyed with **turmeric.**

TABLE I.—REACTIONS OF SALTS OF BI-, TER-, AND QUADRI-VALENT TITANIUM SALTS.

Reagent.	TiO	Ti_2O_3	TiO_2
Aq. ammonia	black	bluish-black	white
Sod. phosphate	bluish-black	bluish-black	white
Sod. oxalate	greenish or brown	yellowish-brown	white
Sod. acetate	greenish or brown	—	white
Pot. ferrocyanide . . .	dark brown	reddish-brown	reddish-yellow
Pot. ferricyanide	reddish-brown	coffee-brown	yellow
Amm. molybdate	dark brown	greenish-black	white
Sodium succinate	greenish-black	greyish-blue	white
Tannin	reddish-brown	yellowish-brown	orange
Pot. thiocyanate and ether .	brown	—	—

The valency and atomic weight of titanium.—J. J. Berzelius,[6] in his early 1813 table of atomic weights, assigned to titanium a value corresponding with an atomic weight of 288·16, if oxygen be 16, but he could not have had much faith in this number since it was omitted from his 1818 table. In 1826, J. J. Berzelius adopted a number equivalent to 48·6, if oxygen be 16, based on the determinations of his pupil H. Rose, which were published in 1829. In these experiments, the amount of titanium dioxide which was formed when ammonia was added to an aq. soln. of titanium tetrachloride, to precipitate titanium hydroxide, and the amount of combined chlorine in the filtered soln. was determined as silver chloride. The earlier and inaccurate result, 61·59 (oxygen 16), obtained by H. Rose by roasting titanium sulphide to titanium dioxide was discarded. Several writers—J. Dalton, J. L. G. Meinecke, L. Gmelin, T. Thomson, L. J. Thénard, P. T. Meissner, O. B. Kühn, and P. F. Cauchy—assigned more or less inexact values to the at. wt. of titanium. In 1829, G. Mosander made some determinations of the amount of oxygen in titanium dioxide and obtained numbers equivalent to an at. wt. ranging from 46·38 to 48·34.

Between the time of J. Dalton's estimate, Ti=40 to 50 (O=7), and the appearance of H. Rose's memoir, there was some doubt whether the formula of titanium dioxide should be written TiO or TiO_2, and the tetrachloride $TiCl_2$ or $TiCl_4$. J. B. A. Dumas[7] measured the vapour density of the chloride, and assuming the formula to be $TiCl_2$, obtained a value equivalent to 30·6 if oxygen be 16 ; and very nearly equivalent to 48 if the formula be $TiCl_4$. This value for the at. wt. of titanium agrees with Avogadro's rule, the sp. ht. rule, the isomorphic law, and the periodic rule. If the value, 48, be accepted for the at. wt., then titanium must be quadrivalent in titanium dioxide, TiO_2, and titanium tetrachloride, $TiCl_4$. In addition, titanium must be bi- and ter-valent respectively in $TiCl_2$ and $TiCl_3$. The analogies between the titanium compounds and those of silicon, tin, and zirconium were emphasized by J. C. G. de Marignac, E. Glatzel, etc. The analogies of tervalent titanium compounds with those of tervalent iron, aluminium, manganese, and chromium were discussed by E. Glatzel, and C. Friedel and J. Guérin. The sexivalency of titanium was emphasized by P. Faber, and the bi-, ter-, quadri-, and sexi-valency of titanium corresponds with the other members of the family—zirconium, and cerium—in the fourth column of periodic table.

In 1847, J. I. Pierre determined the ratio $TiCl_4 : 4Ag$, and found numbers in agreement with 49·91 if oxygen be 16 ; and two years later, A. Demoly, on the assumption that oxygen is 16, obtained 36·2 from the ratio $TiCl_4 : TiO_2$; 56·4

from $TiCl_4 : 4AgCl$; and 43·93 from $TiO_2 : 4AgCl$. Between 1883 and 1885, T. E. Thorpe published a series of determinations of the at. wt. of titanium, and from the ratio $TiCl_4 : 4Ag$ obtained 48·04; from $TiCl_4 : 4AgCl$, 48·06; from $TiCl_4 : TiO_2$, 48·09; from $TiBr_4 : 4Ag$, 48·14; from $TiBr_4 : 4AgCl$, 48·13; and from $TiBr_4 : TiO_2$, 48·08, on the assumption that oxygen is 16. G. P. Baxter and C. J. Fertig obtained between 47·78 and 47·89 from the ratio $TiCl_4 : 4Ag$. From the work available in 1910, F. W. Clarke obtained 48·1, for the best representative value; and B. Brauner, 48·08. The International Table of Atomic Weights for 1925 gave 48·1 for the best representative value for the at. wt. The **atomic number** of titanium is 22. No **isotopes** have been found by F. W. Aston.[8] For the alleged degradation of titanium to carbon, *vide* thorium nitrate. E. Rutherford and J. Chadwick obtained no evidence of the emission of long-range particles when α-particles act on titanium. G. von Hevesy, N. V. Sidgwick, C. P. Smyth, and J. Beckenkamp discussed the **electronic structure** of the atom—*vide* hafnium. H. Petterson and G. Kirsch obtained evidence of **atomic disintegration** when the atoms are bombarded by α-rays.

The uses of titanium.—The pure element has not been used to any great extent, but metal alloys have been used a good deal in ferrous and non-ferrous metallurgy. The ferro-titanium alloys are used as deoxidizers or denitrogenizers in iron and steel metallurgy, and they are also said to impart desirable qualities— *e.g.* toughness to the steel for certain purposes.[9] According to H. Braune,[10] the effect of nitrogen in steel is to increase slightly the toughness, and reduce the ductility. Hard steel with 0·030 to 0·035 per cent. of nitrogen is brittle, and soft steel with 0·05 to 0·06 per cent. loses its ductility. The presence of nitrogen is also said to favour the segregation of phosphorus and sulphur causing cold shortness. Titanium is said to remove the greater portion of the deleterious nitrogen from steel, at about 800°, by forming titanium nitride. For example, some remarkable results have been reported on the improvement of steel rails effected by the use of titanium. Thus, the life of the rails in use is said to have been increased from 200 to 400 per cent. by the titanium treatment. Contradictory results have been reported on the effects produced by titanium in iron because its action depends on the nature and proportions of the various constituents of the sample of iron investigated. Titanium alone does not readily alloy with iron and steel since it floats on the surface of the molten metal, and is difficult to dissolve; *master alloys* are therefore made— ferro-titanium, or ferro-carbotitanium—which when added to molten steel enable any desired proportion of titanium to be added to the metal. Silico-titanium or ferro-silico-titanium has been recommended when it is desirable to add both elements to steel. According to A. J. Rossi,[11] the addition of 1 to 2 per cent. of titanium in molten copper by means of *cupro-titanium* as a master alloy eliminates oxide and absorbed gases and imparts a closer-grained structure than if titanium be absent, *mangano-titanium* is the master alloy which has been advertised as a deoxidizer in bronze manufacture. The effect of titanium on the magnetic properties of iron has been studied by K. P. Applegate—less than 1 per cent. of titanium in Swedish iron lessens the hysteresis losses; and increases the permeability whilst greater amounts increase the hysteresis losses.

Titanium and some of its compounds have been employed in the manufacture of incandescent media for illumination—arc lamp electrodes, filaments for glow lamps, and gas mantles. The use of the metal or of the compounds of titanium —rutile, ilmenite, titanium oxide, or carbide, etc.—for this purpose depends on their high fusion and vaporization temperatures and their high radiation efficiency.[12] Titanic oxide has been recommended in the manufacture of arc-lamp electrodes; and with rutile the results are said to be superior to those with carbon electrodes, particularly for street lighting. The positive electrode in the so- called *magnetite arc lamp* is made from a mixture of magnetite and chromite together with 15 to 25 per cent. of rutile or ilmenite, and it is operated on a direct, not alternating, current. It is claimed that this lamp gives a specially

uniform distribution of light in a horizontal plane. It is also claimed that electrodes made wholly or partially of titanium carbide are comparatively free from the hissing of carbon electrodes, and that they give a steadier light and last longer. The use of titanium filaments for incandescent lamps has not been so successful on account of the rather greater efficiency of tungsten and tantalum filaments. Up to about 2 per cent. of titania in quartz-glass is said to improve the quality.

The salts of the lower oxides of titanium are used as dyes and mordants for producing brilliant stable colours on wool, cotton, and paper. Potassium titanyl oxalate, $TiO.C_2O_4.K_2C_2O_4.H_2O$, is used extensively for this purpose, although titanium trichloride, $TiCl_3$, titanium sesquisulphate, $Ti_2(SO_4)_3$, and the double sulphate of titanium and sodium, $Ti_2(SO_4)_3.Na_2SO_4.5H_2O$, are also employed. The salts are also used in dyeing leather because they do not embrittle the leather so much as iron salts.[13] Titanium trichloride or the corresponding sulphate is used for stripping or removing certain dyes from the goods to enable them to be re-dyed, and in laundries for removing iron stains. In his study of Hungarian red shörl, M. H. Klaproth stated that the purified white earth—titanic oxide—or the powdered native mineral, produces a straw-yellow colour when used as a colouring agent for porcelain glazes. Since that time, titanium oxide and rutile have been employed to a limited extent in pottery for producing ivory and cream colours to withstand high temperatures ; and for colouring artificial teeth. These oxides are also used in the preparation of glazes to give crystalline and opalescent effects. Titanic oxide has been sold under the name T-siloxyd for use in quantities varying from 0·1 to 2·0 per cent. to improve fused silica ware. The use of ferruginous titanic oxide, roasted at different temp. and ground to an impalpable powder, has been patented as a pigment for paints.[14] The tints range from yellow to a brownish-red. Titanium trichloride is a powerful reducing agent, and it has been proposed [15] as a convenient reagent in volumetric analysis—thus, ferric salts can be titrated directly by a standard soln. of this chloride when ammonium thiocyanate is used as indicator. The titration is conducted in an atmosphere of carbon dioxide, to avoid atmospheric oxidation.

§ 7. The Titanium Oxides and Hydroxides

Titanium forms fairly well-defined oxides, *titanium monoxide*, TiO, which is feebly basic ; *titanium sesquioxide*, Ti_2O_3, which is basic, forming a series of characteristic salts ; *titanic acid*, or *titanium dioxide*, TiO_2, which is amphoteric in that it has feebly basic properties and is also acidic in forming the titanates ; and *pertitanic acid* or *titanium trioxide*, TiO_3. The titanosic oxide, $TiO.Ti_2O_3$, or Ti_3O_4, or $Ti(TiO_2)_2$, also called *titano-magnetite*, is not well established. The oxides, Ti_6O_{10}, or Ti_3O_5, and Ti_7O_{12}, have been reported, but the evidence of their chemical individuality is not unequivocal. Hydroxides corresponding with many of these oxides are known.

This is a case where a nomenclature analogous with that recommended by A. Werner [1] —1. 5, 13—is needed. The salts of titanium dioxide are called *titanic* salts ; salts of bivalent and tervalent titanium are both called titanous salts. The monoxide derivatives are so little known that chance of confusion is very small. E. Knecht and E. Hibbert in their monograph on the application of titanium trichloride to volumetric analysis apply the term titanous chloride to salts of tervalent titanium, and this is probably the best expedient until a more satisfactory nomenclature has been adopted.

According to A. Laugier, when titanium dioxide is made into a paste with oil, and heated in a charcoal crucible to a high temp., the outside of the mass has a brown crust ; within is a layer having many cavities and containing yellow particles ; the central, denser mass consists of small, bluish, shining needles, probably of **titanium monoxide,** TiO. Analogous results were obtained by J. J. Berzelius, and P. Berthier. Titanium monoxide was made by H. Moissan in indigo-blue, prismatic crystals by heating titanium dioxide and carbon in the electric arc furnace. Titanium dioxide alone gave this oxide in the electric arc furnace ; when the temp. was too high, titanium nitride was formed. E. Newbery and J. N. Pring found that under a press. of 150 atm. hydrogen reduces titanic oxide at 2000° to the monoxide. H. Rose made it by heating a mixture of titanium dioxide and an excess of zinc in a covered crucible until the zinc passed off as vapour. The mass was then digested with hydrochloric acid, and the titanium monoxide remained as a black powder. C. M. Kersten used an analogous process ; and C. A. Winkler employed magnesium as the reducing agent. M. Billy also prepared this oxide in an analogous way. He said that when a mol of titanium dioxide and 2 gramatoms of magnesium powder are heated to redness, in a current of hydrogen, reduction takes place with incandescence. The product must be allowed to cool in an atm. of hydrogen, as otherwise it readily catches fire in the air. After remaining for a night under glacial acetic acid, it is partially dried at a moderate heat, and then completely dried in a current of hydrogen at 150°. A brown powder is thus obtained, which contains no metallic titanium, but a lower oxide of the metal, mixed with magnesium in the form of magnesium titanate. From the quantity

of oxygen taken up on heating the reduction product, it appears probable that the reaction takes place according to the equation $2TiO_2 + Mg = TiO + MgTiO_3$. According to T. König and O. F. von der Pfordten, when the vapour of sodium is passed over heated titanium dioxide, the product is a mixture of titanium monoxide and sesquioxide.

F. Wöhler, V. Merz, and O. F. von der Pfordten consider that soln. of amorphous titanium in hydrochloric acid contain bivalent titanium, but E. Glatzel believed that a salt of tervalent titanium is present. A similar difference of opinion applies to the blue colour obtained by H. Rose, and P. Berthier by heating a soln. of a salt of titanium dioxide with zinc, tin, iron, or copper. It is probable that many reports in which the blue titanium colour is attributed to a compound of titanium monoxide should really be referred to the sesquioxide. Thus, C. M. Kersten observed that clays containing titanium dioxide may become blue when ignited with deoxidizing agents ; muffles made of such clays and used for the distillation of zinc may acquire in parts a rich violet colour ; the mixture of titaniferous marl and coke dust in the hearths of some Freiburg smelting furnaces exhibit a lavender blue colour ; when glass mixed with titanic oxide and zinc dust is fused, it acquires a violet colour; and when a mixture of silica, alumina, lime, 5 to 10 per cent. of titanic oxide and zinc is calcined, it acquires a fine blue colour. P. Berthier said that the blue colour of many slags is due to the presence of titanium monoxide ; but J. Fournet said the colour is an optical effect caused by the devitrification of the slag. This opinion was supported by C. Mène, and G. Bontemps.

Very little is known about titanium monoxide and that little is unsatisfactory. This oxide exhibits feebly basic properties, furnishing a chloride, iodide, and sulphate (q.v.). According to F. Wöhler, a black precipitate of **titanium dihydroxide,** $Ti(OH)_2$, is produced when ammonia is added to a soln. of titanium in hydrochloric acid ; and it is obtained by adding sodium amalgam to a soln. of titanium sesquioxide in hydrochloric acid. The precipitate is at first blue, and it finally passes into the white dioxide with the evolution of hydrogen. Raising the temp. favours the oxidation. According to O. F. von der Pfordten, the oxidation of the dihydroxide is slower than is the case with the trihydroxide.

C. A. Winkler prepared what he regarded as a hydroxide, Ti_3HO_4, by heating a mol of titanium dioxide and 4 gram-atoms of magnesium powder in a current of hydrogen. After cooling in the hydrogen atm., the product was covered with water in a flask, and hydrochloric acid passed in drop by drop, until present in excess, almost pure hydrogen being evolved. The compound in suspension was collected, washed with hydrochloric acid, alcohol, and ether, and dried over sulphuric acid in vacuo. It forms a black powder, which is not attacked by acids, and evolves hydrogen on treatment with potash-lye, but remains unchanged in appearance. When heated by itself, it also gives off hydrogen without change of appearance, and on ignition in air forms titanium dioxide ; the compound, however, still contains magnesium, probably as magnesium titanate. If in the numbers obtained on analysis the correction be made for a quantity of the latter compound corresponding with the magnesium found, the composition of the remainder is found to be Ti_3HO_4. The decomposition by heat would then be represented by the equation $Ti_3HO_4 = Ti_3O_4 + H$.

G. Rose [2] claimed to have made **titanosic oxide,** Ti_3O_4, by melting a mixture of titanium dioxide and microcosmic salt in a loosely covered crucible. When the glassy product is heated, it becomes opaque owing to the development of octahedral crystals of this oxide—vide infra, R. Brauns. A. Piccini and L. Marino obtained cubic crystals of this oxide by the dry reduction of titanium dioxide. They regard it as a titano-magnetite, $TiO.Ti_2O_3$. By analogy with magnetite, it can also be represented as titanium dititanite, $Ti(TiO_2)_2$, i.e. $O : Ti.O.Ti.O.TiO$.

J. J. Ebelmen [3] heated titanium dioxide strongly in a current of hydrogen, and found it becomes black and loses weight corresponding with the formation of impure **titanium sesquioxide,** or **titanous oxide,** Ti_2O_3. A trace of moisture hindered the reduction. T. König and O. F. von der Pfordten consider that J. J. Ebelmen's observations do not prove that titanium dioxide is reduced to the sesquioxide when heated in a stream of hydrogen ; their product, vide infra, had a different composition. R. Brauns said that crystals of the sesquioxide are formed when titanium dioxide and microcosmic salt are heated in the reducing flame—vide supra, G. Rose. M. Billy made this oxide by the action of titanium

tetrachloride on formic aldehyde followed by a decomposition of the addition product. According to C. Friedel and J. Guérin, this oxide is obtained in the form of minute, lustrous, red crystals together with titanium trichloride and oxychloride when a mixture of hydrogen and titanium tetrachloride is passed over white-hot titanium dioxide. T. König and O. F. von der Pfordten were unable to verify C. Friedel and J. Guérin's observation. J. J. Ebelmen's preparation was an amorphous black mass ; and C. Friedel and J. Guérin's copper-red crystals were isomorphous with hæmatite from Elba, and with ferric oxide, and ferrous titanate, $FeTiO_3$. The titaniferous iron oxides are supposed to be mixtures of ferric oxide and ferrous titanate. The ditrigonal crystals have the axial ratio $a : c = 1 : 1 \cdot 316$, and $\alpha = 87° \, 10'$. P. Groth said that alumina, ferric oxide, chromic oxide, and titanium sesquioxide form an isomorphous family, and that the salts of the different members of this family are also isomorphous. C. Friedel and J. Guérin gave 4·601 for the sp. gr. E. Friedrich and L. Sittig gave 2130° for the m.p., and 18,000 ohms for the electrical resistance at room temp. J. J. Ebelmen found the reoxidation of the sesquioxide is difficult and only proceeds at a very high temp. It is not acted upon by hydrochloric or nitric acid, but forms a violet-blue soln. with sulphuric acid. P. Sabatier and B. Senderens said that when the sesquioxide is heated in nitric oxide or in nitrogen peroxide, it passes into the dioxide with incandescence, without forming the nitrate.

E. Glatzel concluded that no salt of titanium monoxide is present in a soln. of the metal in hydrochloric acid, but a salt of the sesquioxide is formed. When a soln. of titanium tetrachloride is reduced by zinc, copper, or powdered silver obtained by reduction, and treated with ammonia or sodium amalgam, **titanium trihydroxide, titanous acid,** or **titanous hydroxide,** $Ti(OH)_3$, is deposited as a brownish-red precipitate. Observations in this connection were made by J. J. Ebelmen, J. N. von Fuchs, F. von Kobell, W. Manchot and P. Richter, C. F. Rammelsberg, O. F. von der Pfordten, C. Friedel and J. Guérin, and A. Piccini. According to E. Polidori, a soln. of titanium tetrachloride in 30 per cent. hydrochloric acid can be reduced by electrolysis, and when treated with sodium hydroxide gives a black precipitate of titanous hydroxide. T. König and O. F. von der Pfordten obtained titanous hydroxide by the decomposition of *sodium titanite,* Na_3TiO_3, by water. The last-named compound, $Ti(ONa)_3$, or Na_3TiO_3, was said to be formed among the products of the reduction of titanium dioxide by the vapour of sodium. It dissolves in dil. sulphuric acid, forming a violet soln., and it is readily decomposed by water, forming sodium hydroxide and titanous hydroxide ; it is not so readily decomposed by alcohol.

Titanous hydroxide is oxidized with the development of hydrogen : $2Ti(OH)_3 = 2TiO_2 + 2H_2O + H_2$, and at the same time the colour passes through various shades of brown, red, violet, and blue to white. W. Manchot and P. Richter found that when titanium sesquioxide is shaken with an aq. soln. of potassium hydroxide and oxygen, a considerably larger volume of oxygen is absorbed than corresponds with one eq. of oxygen. The hydrogen peroxide primarily formed is reduced partially by the titanium sesquioxide, the remainder of the peroxide oxidizing the titanium dioxide to pertitanic acid on acidification or possibly even in the alkaline soln. If a thick milk of lime or baryta-water is used in place of the potassium hydroxide, the hydrogen dioxide formed is not reduced by the titanium sesquioxide or dioxide, and the whole of the oxygen absorbed is found in the form of hydrogen dioxide. If the soln. of tervalent titanium in sulphuric acid is boiled with potassium hydroxide, it evolves a vol. of hydrogen equal to that of the oxygen absorbed on shaking the alkaline soln. with oxygen. The acid soln. also evolves hydrogen when boiled, but only extremely slowly. When shaken with oxygen, a soln. of tervalent titanium in sulphuric acid containing ferrous ammonium sulphate absorbs a still larger excess of the gas, and the soln. contains ferric oxide, whereas an acid soln. of ferrous ammonium sulphate alone does not absorb a measurable vol. of oxygen. When titanium sesquioxide is added to a soln. of chromic and

hydriodic acids dissolved in the requisite amount of water, the liberated iodine may be estimated by thiosulphate. For the oxidation, 3 gram-atoms of oxygen were required for 1 gram-atom of titanium. The oxidation of titanium sesquioxide with permanganic acid in the presence of tartaric acid also led to a similar result. E. Knecht found that titanium sesquioxide or its hydroxide, prepared by precipitation from a soln. of the trichloride by sodium hydroxide is a powerful solid reducing agent; it converts alkaline nitrate soln. to ammonia; azobenzene to hydrazobenzene, etc. It is a convenient agent for reducing in neutral or ammoniacal soln. without a trace of the reducing agent passing into soln.

According to H. St. C. Deville, if a current of hydrogen chloride accompanied by a reducing agent, say hydrogen, be passed over titanium dioxide at a red heat, small rectangular crystals of deep indigo-blue colour and with the composition Ti_4O_5 are obtained. This may be regarded as $Ti_2O_3.TiO_2$, or **titanyl dititanite**, $TiO(TiO_2)_2$, *i.e.* $O : Ti.O(TiO).O.Ti : O$. The same compound was made by C. Friedel and J. Guérin. M. Billy obtained the oxide in a crystalline form when hydrogen chloride is present. It was assumed by C. F. Rammelsberg that this oxide is present among the products obtained by reducing a soln. of titanium tetrachloride with zinc—*vide supra*. O. F. von der Pfordten supposed that this oxide is formed when heated titanium dioxide is reduced in a current of hydrogen, but he later showed that the composition more nearly approximates to Ti_7O_{12}, or $2Ti_2O_3.3TiO_2$, or **titanous titanate**, $Ti_4'''(TiO_4)_4$.

J. B. L. Romé de l'Isle,[4] and S. R. I. Eques a Born referred to a *schorl rouge ou pourpre*, which, according to R. J. Haüy, is the same as A. L. Lavoisier's *spath adamantin brun-rougeâtre*. A. Estner described *schörlartiger granat;* and M. H. Klaproth a *rother schörl*. All these minerals are regarded as varieties of what R. Kirwan called *titanite*—not what is now known as titanite or sphene. H. B. de Saussure called a variety of *schörl rouge* from the Alps, *sagenite*—from σαγήνη, a net—in allusion to the interlacing and reticulation of the acicular crystals. J. C. Delamétherie called a variety from Crispalt, St. Gothard, *crispite*. A. G. Werner applied the term **rutile** to this mineral in allusion to its colour—*rutilus*, red. R. J. Haüy also called it *titane oxydé*.

W. E. Hidden called a variety from North Carolina *edisonite*—after T. A. Edison. D. L. G. Karsten applied the term *nigrine*—from *niger*, black—to a black ferruginous variety discussed by C. F. Rammelsberg, W. B. Smith, and A. von Lasaulx, and called by W. A. Lampadius, *schwarzer Granat*. H. Rose proved that rutile consists only of titanium dioxide associated with a small quantity of iron oxide. L. J. Igelström called a variety from Dicksberg, Sweden, *dicksbergite*, and M. Weibull and A. Upmark showed that it is rutile. A black mineral from Olary, South Australia, was called *davidite* by D. Mawson, and shown by E. H. Rennie and W. T. Cooke to have about 50 per cent. titanium dioxide, associated with iron rare earths, uranium, vanadium, and chromium; it approximates $FeO.Cb_2O_5.5TiO_2$. J. V. Janovsky found black grains of a mineral which he called *iserite* at Iserwiese, Bohemia; its composition corresponds with $FeTi_2O_5$. A black variety of rutile with over 10 per cent. of ferric oxide obtained by N. von Kokscharoff from the Ilmen Mts., Russia, was called *ilmenorutile*.

J. B. L. Romé de l'Isle referred to a *schorl bleu indigo;* and J. L. Bournon, to a *schorl octaèdre rectangulaire*. Similar minerals were called *octaèdrite* by H. B. de Saussure; *octahedrite*, by J. D. Dana; *oisanite*—from the locality, Bourg d'Oisans, Dauphiné, where it occurred—by J. C. Delamétherie; and *dauphinite*, by E. F. Glocker. R. J. Haüy first called the mineral octaèdrite, but later used the term **anatase**—from ἀνάτασις, erection—in allusion to the fact that c-axis is longer than that of rutile. L. N. Vauquelin showed that the chemical properties of anatase agree with those of rutile; and H. Rose proved that powdered anatase has all the properties of calcined titanium dioxide.

A. Lévy found some rhombic crystals of a mineral from Snowdon, Wales, which he named **brookite**—after H. J. Brooke. W. Haidinger said that F. Soret had previously found a mineral like brookite accompanying the anatase at Bourg d'Oisans, Dauphiné, and P. A. Dufrénoy said that F. Soret called it *zurinite*—after L. Jurine of Genève. According to A. Lacroix, no publication by F. Soret on this subject has yet been traced. F. S. Beudant, indeed, in 1824 said that titanium oxide occurs in nature in two distinct forms, one being rutile, and the

other occurs as *un prisme rhomboïdal.* H. Rose proved that brookite, anatase, and rutile consist of titanium dioxide associated with a little iron oxide.

C. U. Shepard called a mineral from Magnet Cove, Arkansas, *arkansite,* but the observations of A. Breithaupt, J. D. Whitney, W. H. Miller, A. des Cloizeaux and A. Damour, C. F. Rammelsberg, and R. Hermann showed that brookite and arkansite are crystallographically and chemically the same. Another mineral, called *eumanite* by C. U. Shepard, found at Chesterfield, Mass., is assumed by J. D. Dana to be related to brookite.

. The main deposits of rutile [5] are in Amherst and Nelson counties in Virginia ; Quebec (Canada) ; Carinthia ; Transylvania ; near Kragerö (Norway). Ilmenite is one of the chief constituents of the monazite sand of Ceylon and Travancore ; Nigeria, Gold Coast, and Nyassaland (Africa) ; Mount Crawford (South Australia) ; Greenbushes (West Australia) ; Forth district (Tasmania) ; many places in Queensland ; and in the Taranaki sands and various other places on the west coast of New Zealand. Many analyses of rutile have been reported.[6] In the analyses, the iron oxide is usually determined as ferric oxide, but in some cases the iron has been determined in the two states of oxidation :

	Iscrite Iserwiese, Bohemia.	Yellowish-brown rutile.	Vannes black rutile.	Morbihan black rutile.	St. Peter's Dome, Colorado.
TiO_2	68·99	9·76	76·10	55·38	94·93
FeO	1·41	6·23	17·35	36·31	3·77
Fe_2O_3	28·57	3·88	5·41	8·25	0

Pure rutile does not seem to occur in nature, and it is thought that rutile is a solid soln. of titanic oxide, TiO_2, with ilmenite, $FeTiO_3$, and some ferric oxide. In the so-called ilmenorutile, iron tantalate and columbate, $FeO.(CbTa)_2O_5$, are present as well. The mineral is sometimes contaminated with a little oxide of vanadium, chromium, or tin. G. von Hevesy and V. T. Jantzen found no hafnia in the samples of rutile they examined. Samples from Brazil [7] have been reported with 2 to 4 per cent. of stannic oxide, SnO_2, and samples from Black's Hill, Dakota,[8] with 1·3 to 1·4 per cent. C. Friedel and T. Grandjean found 1·75 per cent. of stannic oxide in rutile from Vaux, Rhône. A. G. Ekeberg [9] found 3 per cent. of chromic oxide in a Swedish rutile. H. St. C. Deville reported 0·323 per cent. of vanadic acid, and 0·486 per cent. of molybdic acid in a sample from St. Yrieix ; and, according to H. Rose, 2·0 per cent. of manganese oxide. B. Hasselberg observed vanadium and chromium in samples from many localities. R. J. Haüy called a grass-green variety *titane oxydé chromifère*—chromiferous rutile. Some silica and magnesia are usually present. R. H. Brett and G. Bird described some titanic oxide crystals in clay crucibles. Analyses of anatase were reported by H. Rose,[10] A. Damour, L. N. Vauquelin, J. P. O'Reilly, and E. Hussak ; and of brookite by H. Rose, R. Hermann, A. Damour, K. Romanowsky, and K. Pfeil. All three minerals have the same ultimate composition, and are different crystalline forms of **titanium dioxide,** TiO_2, or **titanic acid.**

Rutile occurs in igneous, metamorphic, and sedimentary rocks ; and it is probably of pyrogenetic origin. It is common in gneiss, mica-schist, and phyllites, and less common in granular limestone and dolomite. A. Bergeat [11] found it along with ilmenite and titanite. T. L. Watson and S. Taber found rutile associated with apatite. Rutile also occurs as a secondary mineral derived from ilmenite and titanite. The slight solubility of rutile in water and in soln. of sodium fluoride, and the crystallization of the mineral in such a soln. after 34 days at 145°, observed by C. Doelter, indicate that some secondary rutile may be derived from the dissolution of primary rutile, or of titanic oxide leached from other rocks. The occurrence of rutile has been discussed by F. Zirkel, E. Kalkowsky, A. Cathrein, H. Behrens, H. Gylling, G. A. Sauer, Comte de Limur, P. Mann, etc. Anatase and brookite appear only as secondary minerals. Anatase occurs in small amounts in rocks of all kinds as an alteration product of titaniferous minerals. The occurrence of anatase has been discussed by E. Hussak, R. Brauns,

A. Lacroix, G. Spezia, A. Schenk, F. Kollbeck, J. S. Diller, O. Mügge, B. Doss, J. B. Scrivenor, H. Rösler, C. Schmidt, K. von Chrustschoff, etc. H. Thürach mentioned the occurrence of brookite and anatase in a great variety of rocks. Brookite alters into rutile ; and rutile into ilmenite, and sphene. The occurrence of brookite has been discussed by A. Müller, J. R. Blum, A. Lacroix, etc.

The preparation of titanium dioxide.—Amorphous titanium dioxide was made by F. Wöhler,[12] and H. Rose by adding aq. ammonia to a soln. of titanium tetrachloride, washing and calcining the precipitate ; it is also made by the processes indicated in connection with the extraction of titanium—*vide supra*—namely, by fusing rutile or titanic iron ore with potassium carbonate, decomposing the mass with hydrofluoric acid ; separating and crystallizing the resulting potassium fluotitanate, and decomposing its hot soln. with aq. ammonia ; or by heating titanic iron ore in a stream of chlorine and hydrochloric acid—the iron is volatilized as chloride, and the titanium dioxide remains : $2FeTiO_3 + 4HCl + Cl_2 = 2FeCl_3 + 2TiO_2 + 2H_2O$. H. Geisow described the extraction of titanium dioxide from rutile, etc. ; and C. Winkler, and G. Cartaret and M. Devaux, the purification of commercial titanium dioxide. J. J. Ebelmen showed that if the amorphous titanium dioxide be heated with boric acid, or better, with microcosmic salt, in a pottery oven, golden yellow, acicular crystals of rutile were formed. According to G. Wunder, the crystals are sodium phosphotitanate, and not anatase as G. Rose assumed, or titanyl phosphate, $TiO(PO_3)_2$, as A. Knop supposed ; on the other hand, R. Brauns believed them to be titanium sesquioxide, and L. Ouvrard, rutile with titanyl phosphate and alkali titanophosphate. G. Rose, and A. Knop obtained fine crystals of rutile by heating for a long time amorphous titanium dioxide mixed with borax, or with borax and microcosmic salt. B. Doss used borax. J. J. Ebelmen also obtained rutile by heating the amorphous dioxide with potassium carbonate. H. St. C. Deville and H. Caron prepared rutile by heating to redness a mixture of amorphous titanium dioxide, silica, and stannic oxide. L. Bourgeois used barium chloride as a flux ; F. A. Genth, potassium hydrosulphate ; and P. Hautefeuille, sodium silicate, tungstate, or vanadate ; H. Cormimbœuf melted titanium dioxide with sodium carbonate, sodium tungstate, and as much tungstic oxide to make the composition of the fused tungstate that of the normal tungstate-crystals of rutile are formed ; with less tungstic acid, crystals of the alkali titanate are formed. H. Traube also used sodium tungstate as *agent minéralisateur*, and he was able to add to the rutile appreciable quantities of iron, manganese, and chromium which are present as impurities in the natural mineral. T. Scheerer observed crystals of rutile in the cracks of the brickwork of a blast-furnace ; and K. Endell, in pottery glazes containing 5 to 10 per cent. of rutile. H. E. Merwin and J. C. Hostetter obtained crystals of rutile by the action of chlorine on titaniferous clays at 1000°–1100°. F. Wöhler heated titanium nitride in air, and obtained crystals of what were thought to be rutile. L. Michel obtained a mixture of rutile and pyrrhotite by heating a mixture of ilmenite and pyrite. H. de Sénarmont heated amorphous titanium dioxide in the presence of carbon dioxide in a sealed tube at 200°. A. Daubrée decomposed titanium tetrachloride by steam at a red heat and obtained crystals of the dioxide ; and H. St. C. Deville passed hydrogen fluoride or chloride over red-hot titanium dioxide and obtained crystals of rutile ; if a reducing atm. be present, blue crystals of $TiO(TiO_2)_2$ were formed. Similar results were obtained by P. Hautefeuille and A. Perrey. The three forms of titanium dioxide were studied by P. Hautefeuille. A mixture of potassium titanate and potassium chloride heated to redness in a stream of dry air mixed with hydrogen chloride furnished crystals of rutile. Similar crystals were obtained by heating to redness a mixture of titanium dioxide and potassium fluoride or calcium fluoride, or a mixture of titanium dioxide and potassium fluosilicate in hydrogen chloride. In these experiments, if the temp. exceeded 1040°, rutile was formed ; between 800° and 1040°, brookite ; and below 800°, anatase. O. Lehmann discussed the transformation of one form into another. C. Friedel and J. Guérin heated to

redness titanium chloride and ferrous oxide, and obtained ferrous chloride and crystals of titanium dioxide ; and by passing chlorine over titanium-iron at a red heat, ferric chloride is volatilized and crystals of rutile are formed. They proposed the reaction as a means of separating titanium from iron.

F. Wöhler heated titanium carbonitride in a current of steam and obtained crystals of anatase ; and H. Rose obtained anatase by heating amorphous titanium dioxide for a short time by means of a spirit-lamp. G. Rose found some crystals of anatase in the product obtained from a soln. of titanium dioxide in molten microcosmic salt. The process was examined by A. Knop, G. Wunder, B. Doss, and L. Ouvrard. F. A. Genth found that some anatase accompanied the rutile when titanium dioxide was fused with potassium hydrosulphate. B. Doss' attempts to make anatase with fused borax as *agent minéralisateur* were not successful, rutile was always formed. P. Hautefeuille obtained anatase by the decomposition of titanium tetrafluoride by aq. vapour, at or near 860° ; and also by heating titanium trifluoride in a current of air. P. Hautefeuille and A. Perrey found that hydrogen chloride has no action on titanium dioxide at a bright red heat, but under a press. of 3 atm., anatase is formed at a dull red heat ; at the same temp. and under ordinary atm. press., hydrogen chloride has a mineralizing effect on the carbonate, oxalate, or sulphate, but not on the oxide.

A. Daubrée made crystals of brookite by passing a mixture of the vapour of titanium tetrachloride, steam, and carbon dioxide through a red-hot tube ; and also when the vapour of titanium tetrachloride is decomposed by heated lime. P. Hautefeuille found that brookite is formed when potassium fluotitanate is heated in steam, and when hydrogen fluoride acts on titanium tetrachloride at a temp. not exceeding 1040°. A mixture of titanium dioxide, calcium fluoride, and potassium heated in a stream of hydrogen chloride, silicon tetrafluoride, and moist hydrogen, also furnished crystals of brookite, and a similar result was obtained when a mixture of titanium dioxide, silica, and potassium fluosilicate was heated in a current of hydrogen chloride alone. B. Doss obtained rutile, not brookite, from soln. of titanium dioxide in fused borax.

The physical properties of titanium dioxide.—Purified titanium dioxide is colourless ; the **colour** of the mineral forms is due to the presence of impurities, is usually reddish-brown passing into red, and sometimes yellowish, bluish, violet, black, and rarely, grass-green. In transmitted light the colour is yellow, various shades of red, and violet. Anatase may be various shades of yellow and brown ; and sometimes indigo-blue or black. In transmitted light, the same colours may appear, and they are sometimes distributed zonally or irregularly. Brookite may be yellowish- or reddish-brown or iron-black. In transmitted light the colour may be yellowish, reddish, brownish, or colourless, and rarely blue or bluish-green J. W. Retgers [13] said the colour of rutile is largely determined by the titanium dioxide and not by the ferric oxide. L. Wöhler and K. von Kraatz-Koschlau obtained colours ranging from bluish-black to greenish-black with titanium sesquioxide as the tinctorial agent. Red rutiles were obtained only with the ferric oxide ; vanadium oxide had no effect on the colour. H. Traube melted mixtures of rutile with ferric oxide and obtained a dark brown product with 1·98 per cent., and a black mass with 5·4 per cent. of ferric oxide ; manganese oxide gave a yellow tint, and the colour was bluish-black when 3 per cent. of this oxide was present. With chromic oxide, a green colour was obtained. R. F. Wagner said that the colour of titanium dioxide is determined by the treatment it has received. When moist orthotitanic acid is heated, there is a remarkable play of colours. The oxide becomes almost white when cold and citron-yellow when hot, and by continued heating the colour becomes more and more brownish.

O. Hahn [14] studied the surface area of the particles of different forms of precipitated titanic oxide in terms of adsorbed radioactive matter. The habit of the euhedral **crystals** of rutile is commonly prismatic with furrows or striations on the surface parallel to the *c*-axis. The crystals are often acicular, very slender,

or hair-like. Transparent quartz is sometimes penetrated thickly with acicular or capillary crystals as illustrated by Fig. 6. This furnishes the so-called *sagenite* and *crispite* alluded to above; and the *veneris crinis* of Pliny's *Historia Naturalis* and the so-called *flêches d'amour* or *Venus' hair stone* are varieties of quartz penetrated with acicular rutile. Rutile occurs compact and massive, and in granules. Anatase is usually octahedral, in habit acute or obtuse, and also tabular. It is rarely prismatic. The habit of brookite crystals is varied. The euhedral crystals are often tabular parallel to the (100)-face; with the (100)-face and the prismatic faces striated vertically. Sometimes the habit is prismatic with the (110)-face dominant, resembling rutile. According to R. J. Haüy, crystals of rutile belong to the tetragonal system; and more exact measure-

FIG. 6.—Rutile Needles in Quartz.

ments were made by A. Breithaupt, G. A. Kenngott, and W. H. Miller. The last-named gave for the axial ratio $a : c = 1 : 0.644154$; H. Baumhauer, $1 : 0.6439$; and N. von Kokscharoff, $1 : 0.64418$. The optical anomalies of rutile led E. Mallard to assume that it does not belong to the tetragonal system; and F. Wallerant regarded rutile as monoclinic. G. Friedel, and W. J. Sollas considered the space-lattice to be tetragonal. Observations on the crystals of rutile were made by H. Baumhauer, R. L. Parker, G. vom Rath, F. Hessenberg, C. O. Trechmann, F. Pisani, O. Lincio, H. Tertsch, A. von Lasaulx, W. C. Brögger, P. von Jeremejeff, G. Tschermak, F. Rinne, D. Brewster, O. Mügge, M. Bauer, L. Cahn, G. Rose, H. S. Washington and W. E. Hidden, etc. The crystals of anatase were examined by R. J. Haüy who placed them in the tetragonal system and the cognomen, as previously indicated, implied that the c-axis is longer than is the case with rutile. W. H. Miller gave for the axial ratio $a : c = 1 : 1.7771$. Observations were made by C. Klein, A. des Cloizeaux, O. Luedecke, C. Vrba, A. Frenzel, A. Stelzner, R. L. Parker, O. Pohl, F. Wiser, G. vom Rath, A. Brezina, G. Boeris, A. Lévy, H. Buttgenbach, J. Beckenkamp, G. Cesaro, R. W. Haare, O. C. Farrington and E. W. Tillotson, H. P. Whitlock, W. Prinz, J. Schetelig, S. L. Penfield, L. Colomba, A. Johnsen, H. Baumhauer, F. Millosevich, G. Seligmann, A. Sella, A. Streng, E. Bertrand, F. Hessenberg, C. Busz, A. E. Robinson, etc. The crystals of brookite, said F. S. Beudant, were *confondue pendant long-temps avec le rutile*. A. Lévy found that they belonged to the rhombic system. N. von Kokscharoff gave for the axial ratios $a : b : c = 0.84158 : 1 : 0.94439$. The crystals were measured by K. Romanowsky, W. H. Miller, and A. des Cloizeaux. A. Schrauf tried to show that the crystals of brookite are really monoclinic, but both N. von Kokscharoff and P. Groth showed that this is not a correct interpretation. Further observations were made by C. Vrba, G. Lechner, A. Wichmann, F. Wiser, C. Palache, A. Fornaro, L. Brugnatelli, G. vom Rath, C. Busz, G. Rose, P. von Jeremejeff, G. F. Kunz and S. L. Penfield, A. Breithaupt, E. S. Dana, etc. In addition to the three forms, rutile, anatase, and brookite, R. B. Riggs and J. S. Diller reported a fourth rhombohedral form occurring in thin iron-black scales as inclusions in the tourmaline of Hamberg, New Jersey, and De Kalb, New York. J. D. Dana, however, regarded it as a variety of ilmenite.

The **twinning** plane and composition plane (101) of rutile are often geniculated, and there are contact twins of very varied habit. There is also polysynthetic twinning in thin lamellæ parallel to (101), and the lamellæ are of various lengths,

and distributed irregularly in the crystals. The **cleavage** of rutile parallel to (110) and (100) is distinct; and that parallel to (111) is in traces. This subject was studied by A. Breithaupt, G. A. Kenngott, W. H. Miller, etc. O. Mügge [15] reports a parting due to twinning parallel to (902). The cleavage of anatase parallel to (001) and (111) is perfect; and those of brookite parallel to (110) and (001) are indistinct and seldom observed in microscopic crystals. The **corrosion figures** of rutile with molten potassium fluoride, or hydrofluoride, were studied by H. Traube. Naturally etched crystals of anatase, and crystals etched with potash-lye were studied by H. Baumhauer; and the gliding planes of rutile, by A. Grühn and A. Johnsen. Observations on the **optic axial angle** of brookite were made by A. Beer,[16] W. H. Miller, J. Grailich and V. von Lang, etc. J. Grailich gave $2E=65°$ for the red ray; and A. Schrauf gave:

λ	691	670	661	592	589	555	534	532	486
$2E$	58° 22′	55° 2½′	50° 45′	28° 56′	30° 16½′	0	33° 48′	38° 7′	c. 70°

A. des Cloizeaux measured the effect of temp., and found that by raising the temp. to redness, $2E$ changed from 42° to 47°; and U. Panichi changed $2E$ from 54° to 26° by cooling to $-190°$.

Anatase is isomeric but not isomorphous with rutile. The **X-radiogram** has been studied by L. Vegard,[17] H. Haga and F. M. Jäger, W. P. Davey, J. Becken-kamp, H. Tertsch, G. Greenwood, A. Johnsen, R. L. Parker, M. Born and O. F. Bollnow, and C. M. Williams. According to L. Vegard, in the space-lattice of zircon, $ZrSiO_4$, the oxygen atoms are arranged in pairs about the zirconium and silicon atoms, and he considers that the constitutional mol. formula of zircon is accordingly $ZrO_2.SiO_2$, not $ZrSiO_4$. The space-lattice of anatase can be derived from that of zircon by removing the zirconium atoms and their associated oxygen atoms, and substituting titanium atoms for the silicon atoms. The oxygen atoms are arranged in line with the titanium atoms with the lines parallel to the tetra-gonal axis. Hence, L. Vegard writes the mol. formula TiO_2. The estimated absolute dimensions of the space-lattices of rutile and anatase are given in Table II. C. M. Williams's data do not agree with those of L. Vegard, and he

TABLE II.—DIMENSIONS OF THE SPACE-LATTICES OF RUTILE AND ANATASE.

	Crystal axes in cm.			Volume in c.c.	Distance between the central Ti atom and the O atom cm.
	a	c	$a : c$		
Rutile, $(TiO_2)_2$	9.05×10^{-8}	5.8×10^{-9}	$1 : 0.644$	4.77×10^{-22}	1.99
Anatase, TiO_2	5.27×10^{-8}	9.37×10^{-8}	$1 : 1.777$	2.60×10^{-22}	1.95

assigns to the crystal unit a different structure. According to M. L. Huggins, in rutile and anatase, each titanium atom is surrounded by four equidistant oxygen atoms, and each oxygen atom by two equidistant titanium atoms, all at tetrahedron corners. F. Rinne represents the arrangement in the tetragonal unit by the drawing, Fig. 7. The observed data are not yet sufficient to establish the structures of anatase and rutile.

FIG. 7.—The Tetragonal Unit of Rutile—F. Rinne.

G. Rose [18] assumed that rutile, zircon, and cassiterite are isomorphous; and P. Groth wrote the formulæ $TiTiO_4$ and $SnSnO_4$, in order to emphasize their relationship to $ZrSiO_4$. He also considered brookite to be related to tridymite, and anatase to cristobalite. J. W. Retgers did not agree with the assumption that these minerals are isomorphous, and maintained that there is a chemical contrast between zirconium and silicon which is not characteristic of isomorphism; titanium and silicon dioxides, said he, *nicht die geringste Neigung zu inniger Mischung zeigen—*
this is illustrated by the rutile needles found in colourless crystals of quartz. Further, tin dioxide does not appear to be miscible with titanium or zirconium dioxide. Against J. W. Retgers' view, H. Traube found that the corrosion figures of rutile, zircon, and cassiterite show the holohedral tetragonal symmetry. Some crystallographic data for the minerals rutile, $TiTiO_4$; zircon, $ZrSiO_4$; cassiterite, $SnSnO_4$; thorite, $ThSiO_4$, polianite, $MnMnO_4$; and plattnerite, $PbPbO_4$, by S. Stevanovic, are shown in Table III. The mol. vol. axis ratios, and the topic axes increase with the

TABLE III.—CRYSTALLOGRAPHIC PROPERTIES OF THE ISOMORPHOUS DIOXIDES.

Mineral.	Mol. wt.	Sp. gr.	Mol. vol.	$a : c$	Topic parameters $\chi : \omega$
Rutile, TiO_2 .	80·1	4·24	18·85	1 : 0·6441	2·081 : 1·984
Polianite, MnO_2	87·0	5·04	17·26	1 : 0·6647	2·960 : 1·969
Zircon, $(Zr,Si)O_2$	91·50	4·70	19·48	1 : 0·6404	3·122 : 1·999
Cassiterite, SnO_2	150·0	7·018	21·44	1 : 0·6726	3·608 : 2·136
Thorite, $(Th,Si)O_2$.	162·45	5·40	30·80	1 : 0·6402	3·176 : 2·310
Plattnerite, PbO_2 .	238·0	8·50	28·11	1 : 8·6764	3·468 : 2·345

mol. wt. except in the case of polianite, which probably does not belong to the series, as is also the case with silica. H. Buttgenbach, V. Goldschmidt, A. Schrauf, G. Wunder, R. Ruer, G. Linck, W. T. Schaller, and M. Ladrey emphasized the crystallographic relationshp between the dioxides of tin, titanium, and zirconium. O. Lehmann discussed the transformation of one modification of titanium dioxide into the other.

M. H. Klaproth [19] gave 4·180 for the **specific gravity** of titanium dioxide and C. J. B. Karsten gave 3·9311. H. Rose found that when heated to 600°, the sp. gr. of the amorphous precipitate rose from 3·89 to 3·95; after exposure to a stronger source of heat for a longer time at 800°, 4·13; and after vigorous calcination at 1000°–1200°, 4·255. P. Hautefeuille found that after fusion and pulverization, the sp. gr. was 4·1. H. Fizeau said that artificially prepared rutile has the same sp. gr. as the mineral. For rutile, C. M. Kersten gave 4·242; A. Virlet, 4·325–4·246, and after fusion, 4·241; M. Weibull and A. Upmark, 4·2; R. Böttger, 4·249; T. Scheerer, 4·244–4·245; A. Breithaupt, 4·250–4·291; H. Kopp, 4·420 at 0°; H. Müller, 4·56; A. von Lasaulx, 4·173–4·278. H. Geisow gave 4·21 for the sp. gr. of the strongly calcined oxide. For artificial rutile, J. J. Ebelmen found 4·260–4·283; and P. Hautefeuille, 4·3. A. des Cloizeaux and A. Damour found the sp. gr. of rutile rose from 4·273 to 4·365 when heated in a current of hydrogen. Rutile containing appreciable amounts of tin or iron oxides has a higher sp. gr. For instance, W. B. Smith found a sp. gr. 4·288 for a sample with 3·77 per cent. of ferrous oxide; F. A. Genth, 4·249 for a sample with 6·68 per cent. of ferric oxide; and W. P. Headden, 5·294 for samples with 7·92–8·10 per cent. ferrous oxide. L. N. Vauquelin gave for the sp. gr. of anatase, 3·857; N. von Kokscharoff, 3·815; E. Hussak, 3·794; F. Mohs, 3·826; A. Breithaupt, 3·750; C. Klein, 3·83–3·97; A. des Cloizeaux, 3·87; F. von Kobell, 3·82; H. Rose, 3·890–3·912; and A. Damour, 4·06. For artificial anatase, P. Hautefeuille gave 3·7–3·9. The sp. gr. of brookite by H. Rose ranged from 4·128 to 4·166, and on calcination, the sp. gr. became the same as that of rutile; A. Breithaupt gave 3·952; C. F. Rammelsberg, 3·892–3·949; A. Damour, 4·030–4·083; J. D. Whitney, 4·085; W. von Beck, 4·200; M. Frodmann, 4·220; K. Romanowsky, 4·1–4·2; R. Hermann, 3·83; and N. von Kokscharoff, 4·1389–4·1410. P. Hautefeuille gave 4·1 for artificially prepared brookite.

J. D. Dana [20] tried to show that there is a simple relationship between the **molecular volume** and the crystallographic constants of minerals; and he concluded that the relationship depended on mol. vol., and had nothing to do with chemical composition. G. T. Prior applied the theorem to estimate possible

values for the mol. wt. of the three forms of titanium dioxide. In the case of rutile and zircon, the mol. vols. 19 and 39 respectively, are nearly equal when the mol. vol. of rutile is doubled. This would make the mol. wt. of rutile Ti_2O_4, or $TiTiO_4$. The close similarity of anatase with a mol. vol. 20, with calomel, mol. vol. 72, and matlockite, Pb_2OCl_2, mol. vol. 70, suggests that the mol. vol. of anatase is 80, in agreement with Ti_4O_8. Likewise with the series brookite, mol. vol. 19·6 ; tantalite, $FeTa_2O_6$, mol. vol. 62·32 ; and hübnerite, $MnWO_4$, mol. vol. 42·133, approximate equality is obtained by multiplying by these values respectively by 6, 2, and 3. This gives a mol. wt. for brookite in agreement with Ti_6O_{12}. A. Schrauf represented rutile by $Ti_{22}O_{44}$, anatase by $Ti_{40}O_{80}$, and brookite by $Ti_{43}O_{86}$; he considered anatase to be a titanyl compound $\{(TiO)O\}_{40}$. G. T. Prior also pointed out that the principle did not apply in the case of the homomorphous minerals, zincite, ZnO_2, greenockite, CdS, and iodyrite, AgI ; and in the case of scorodite, $FeAsO_4.2H_2O$, and gypsum, $CaSO_4.2H_2O$, and the case of pucherite, $BiVO_4$, and celestine, $SrSO_4$—*vide* anorthite. F. A. Henglein, and G. von Hevesy compared the mol. vol. of the titanium, zirconium, hafnium, thorium, and cerium oxides. The **hardness** of rutile, etc., on Mohs' scale is indicated in Table IV, in

TABLE IV.—THE POLYMORPHOUS TITANIUM DIOXIDES.

	Sp. gr. D	Hardness.	Crystal vol., v	vD	Ratios of $v : D$	Mean refractive index, μ	$\dfrac{\mu - 1}{D}$	Optical character.
Anatase . .	3·840	5·5–6·0	0·7108	2·7496	2·73	2·5011	0·3909	Negative
Brookite .	4·065	5·5–6·0	0·6667	2·7101	2·71	2·5872	0·3905	Positive
Rutile .	4·239	6·0–6·5	0·6440	2·7300	2·73	2·6642	0·3926	Positive

which some properties of the polymorphous forms of titanium dioxide are compared. The hardness was discussed by A. Reis and L. Zimmermann. J. A. Deurs and P. E. Raaschou studied the viscosity of suspensions. E. Madelung and R. Fuchs found the **compressibility** of rutile to be $3·27 \times 10^{-12}$ dynes per sq. cm. P. W. Bridgman also measured the linear compressibility of rutile, and found at 30° $\delta l/l_0 = 1·038p - 0·70p^2$; and at 75° $\delta l/l_0 = 1·090p - 0·70p^2$ when taken parallel to the tetragonal axis ; p denotes press. ranging up to 12,000 kgrms. per sq. cm.

H. Kopp [21] gave for the coeff. of cubical **thermal expansion** of rutile, 0·000032 between 14° and 46° ; and H. Fizeau gave $0·0_42347$ at 40°, and for the coeff. of linear expansion of rutile parallel to the chief axis, $\alpha = 0·0_5919$, and perpendicular to that axis, $\alpha = 0·0_5714$; A. Schrauf gave respectively $0·0_59943$ and $0·0_57192$ for rutile at 17·5°. H. Fizeau gave $0·0_5819$ in the direction of the axis of isotropy of anatase, and when perpendicular to that axis, $0·0_5468$ at 40° ; and A. Schrauf gave respectively $0·0_566724$ and $0·0_528801$ at 17·5° ; the last-named also gave for the three axes of brookite, $0·0_4144938$, $0·0_4192029$, and $0·0_4220489$. H. de Sénarmont found the principal axis of rutile to be the long axis of the isothermal ellipsoid, and, according to E. Jannetaz, the ratio of the square roots of the **thermal conductivity** in the direction of the principal axis and of the base is 0·826 for rutile, and 1·34 for anatase. F. E. Neumann gave 0·1724 for the **specific heat** of rutile between about 15° and 100° ; H. Kopp gave 0·157 for rutile between 16° and 47°, and 0·161 for brookite between 19° and 49°. H. V. Regnault gave 0·17164 for titanium dioxide between 16° and 98° ; and A. Schuller and V. Wartha, 0·1779– 0·1785. L. F. Nilson and O. Petterson found 0·1784–0·1787 for rutile between 0° and 100° ; 0·1790–0·1792 between 0° and 211° ; 0·1841–0·1844 between 0° and 300° ; and 0·1906–0·1931 between 0° and 440°. The corresponding **molecular heats** were 14·25, 14·29, 14·70, and 15·30 respectively. Like stannic oxide, white titanium dioxide becomes yellow and then brown when heated, and E. D. Clarke fused titanium dioxide in the oxyhydrogen flame. F. Born estimated titanic oxide to be **dissociated** to the extent of 10^{-18} into oxygen and metal at 2000°. The **melting**

point of rutile found by R. Cusack was 1560°; C. Doelter gave 1980°; O. Ruff and co-workers, 1640°; and A. L. Fletcher, 1610°. R. Cusack gave for brookite, 1610°; R. Rieke gave for the m.p. of titanium dioxide, 1610°—*vide* titanium silicates. W. R. Mott showed the **boiling point** of titanium dioxide to be below 3000°. W. G. Mixter found for the **heat of formation** of amorphous titanium dioxide by heating the metal with sodium dioxide : $Ti+O_2=TiO_2+215\cdot6$ Cals. ; and for the heat of oxidation of the metal, 218·4 Cals. ; L. Weiss and H. Kaiser gave 97·772 Cals.

The **indices of refraction** of rutile were measured by K. Bärwald,[22] O. Mügge, and G. Lincio. According to P. Ités, for rutile :

	B-line.	C-line.	D-line.	E-line.	b-line.
ω . . .	2·5469	2·5624	2·6030	2·6664	2·6795
ϵ . . .	2·8186	2·8377	2·8899	2·9669	2·9838

Values for anatase were obtained by D. Brewster, C. Klein, O. Pohl, etc. E. A. Wülfing gave for Li-light, $a=2\cdot5183$, and $\omega=2\cdot4523$; for Na-light, $a=5618$, and $\omega=2\cdot4886$; and for Tl-light, $a=2\cdot6066$, and $\omega=2\cdot5262$. He also gave for brookite with Li-light, $a=2\cdot5408$, $\beta=2\cdot5418$, and $\gamma=2\cdot6444$; with Na-light, $a=2\cdot5832$, $\beta=2\cdot5856$, and $\gamma=2\cdot74114$; and with Tl-light, $a=2\cdot6265$. The **birefringence** of rutile is strong; from P. Ites' data, $\gamma-a=0\cdot2864$. A. Ehringhaus and H. Rose compared the dispersion and double refraction of the dioxides of silicon, titanium (rutile and anatase), and tin with their mol. wts. The **optical character** of anatase is negative, and the optical characters of rutile, and brookite are positive. The crystals may show an **optical anomaly.** E. Mallard found rutile may appear abnormally biaxial, and, as indicated above, he assumed that the crystals are normally rhombic or monoclinic. The phenomenon with rutile was also studied by A. Madelung, and A. von Lasaulx ; and with anatase, by A. Madelung, E. Mallard, A. des Cloizeaux, and A. von Lasaulx. The **pleo-chroism** of the crystals of rutile was studied by H. Traube ; those of anatase by C. Klein, A. von Lasaulx, and E. Weinschenk ; and those of brookite, by H. Thürach, J. Grailich, A. Michel-Lévy and A. Lacroix, and L. Brugnatelli. J. Joly attributed pseudo-opaque patches in crystals of anatase to internal multi-reflections. According to J. Königsberger, the **ultra-violet absorption spectra** of rutile, anatase, and brookite have maxima at $0\cdot380\mu$; V. von Agafonoff found anatase to be transparent for ultra-violet light as far as the cadmium line, and rutile, as far as the line 3μ. P. Ites also studied the absorption and extinction coeff. of rutile. W. W. Coblentz found the **ultra-red transmission spectrum** of brookite showed no bands, but there was a depression in the curve at $3\cdot1\mu$; rutile was rather more opaque than brookite. The **ultra-red reflection spectrum** of rutile had maxima at $10\cdot1\mu$, $10\cdot6\mu$, 11μ, $11\cdot7\mu$, and $13\cdot6\mu$; and the **ultra-red emission spectrum** had maxima at $2\cdot4\mu$, $3\cdot2\mu$, $5\cdot5\mu$, and $7\cdot0\mu$. The mineral has a bright red colour at 1000°. T. Liebisch and H. Rubens studied the reflecting power of rutile for the long infra-red rays ; and H. R. Robinson, and D. Coster, the **X-ray spectrum.** A. de Gramont studied the **spark-spectrum** of rutile, anatase, and brookite. N. von Kokscharoff observed a **thermoluminescence** with a reddish-yellow glow, when anatase is heated. The **calorescence**—5. 33, 10—of titanium oxide was studied by J. J. Berzelius, L. Wöhler, M. E. Chevreul, G. Wagner, and H. Rose. J. Böhm showed by X-radiograms that the phenomenon is connected with the passage from the amorphous to the crystalline state. E. L. Nichols and co-workers studied the flame luminescence and spectrum of incandescent titanium dioxide as well as the luminescence in **ultra-violet light,** and in the **cathode rays**—ultra-violet light did not excite luminescence. H. J. Spanner studied the emission of electrically charged particles by heated titania. W. Crookes, and E. L. Nichols observed the luminescence of rutile when exposed to the cathode rays. C. Doelter found brookite to be more transparent than rutile to the **X-rays.**

According to F. Beijerinck,[23] the **electrical conductivity** of rutile, anatase,

or brookite is inappreciable at ordinary temp., and C. Doelter said that this remark also applies to rutile below 950°; at 1150°, the sp. resistance of a plate of rutile is 950 ohms, and at high temp. the mineral conducts very well. W. Schmidt found the **dielectric constant** of rutile to be greater than that of any other mineral he examined, being 173 parallel to the principal axis; 89 perpendicular to that axis; and 117 when in the powdered form. For brookite, W. Schmidt gave 78; and for powdered arkansite, 12. The Metal and Thermite Corporation, and S. J. Lubowsky prepared a conducting mixture by heating the dioxide in a reducing atm. E. T. Wherry found rutile showed no evidence of the rectification required by a radio-detector; but octahedrite and brookite were fair radio-detectors. H. S. Roberts and L. H. Adams also discussed this subject. B. Bavink studied the **magnetic properties** of rutile.

The **hydrates of titanium dioxide.**—H. Rose,[24] and A. Knop obtained **colloidal titanium dioxide** in a gelatinous form during the separation of iron from titanium by adding tartaric acid to a hydrochloric acid soln.; on the addition of aq. ammonia, the titanium oxide is precipitated as a gelatinous mass. This is washed with water. E. A. Schneider used a similar process and purified the gelatinous product by dialysis. O. F. von der Pfordten melted a mixture of titanium dioxide and potassium carbonate, and digested the product with 36 per cent. hydrochloric acid without warming. The gelatinous residue was washed with cold water. T. Graham obtained the hydrosol of titanium dioxide by dialyzing a soln. of precipitated titanium dioxide in hydrochloric acid; with conc. soln., a hydrogel is formed. He said:

Liquid titanic acid is prepared by dissolving gelatinous titanic acid in a small quantity of hydrochloric acid, without heat, and placing the liquid upon a dialyzer for several days. The liquid must not contain more than one per cent. of titanic acid, otherwise it gelatinizes spontaneously, but it appears more stable when dilute.

Titanium dioxide thus resembles silica very closely in its power of forming colloidal sol and gel. S. Klosky and C. Narzano obtained the best results in the preparation of the gel by coagulating a soln. of the composition $HCl + TiO_2.nH_2O$ with potassium, sodium, or ammonium carbonates. S. Glixelli studied the electrosmosis of titanic acid; and K. van der Grinten, the cataphoresis. T. Graham also made *titanic alcogel, titanic etherogel, titanic sulphatogel,* and *titanic glycerogel* analogous to the corresponding compounds with silica. As in the analogous case of silica, it is believed that there exists an orthotitanic acid, H_4TiO_4, or $Ti(OH)_4$; a metatitanic acid, H_2TiO_3, or $TiO(OH)_2$; and possibly other condensed forms. What is here called orthotitanic acid was called by H. Rose *α-titanic acid;* and metatitanic acid, *β-titanic acid.* As H. Geisow emphasized, the hydroxide has but a feeble acidic character, the basic character is marked. T. Carnelley and J. Walker found that the dehydration curves of silicic and titanic acids exhibit no breaks or evidence of the formation of definite hydrates. The titanates do not exhibit the degree of complexity characteristic of the silicates. A form of titanic acid analogous to the so-called *β*-stannic acid has not been prepared. A comparison of the stannic and titanic acids was made by H. Rose and R. Weber, and C. F. Rammelsberg.

According to H. Rose,[25] **orthotitanic acid,** $Ti(OH)_4$, or H_4TiO_4, is obtained as a voluminous white precipitate when ammonia, or an alkali hydroxide or carbonate is added to soln. of titanium dioxide in hydrochloric or sulphuric acid, prepared in the cold. It is also formed by decomposing potassium titanate with hydrochloric acid. The precipitate is washed with water and dried in the cold. If the temp. is raised, some metatitanic acid is formed. According to K. Bornemann and H. Schirmeister, orthotitanic acid may be precipitated from hot strongly acid soln. by the addition of ammonia without destroying its solubility in dil. acids. When metatitanic acid is dissolved in conc. sulphuric acid, boiling for more than a few minutes must be avoided, or an insoluble precipitate is formed. No difference in this respect is observed between ortho- and meta-titanic acids. G. Wagner

also found that the ortho-acid gradually passes into the meta-acid if it is allowed to stand for long in contact with water. According to L. Weiss and M. Landecker, when orthotitanic acid is washed with water, the filtrate is very prone to turbidity, but not if the washing liquid be 0·5 per cent. aq. ammonia ; or about one per cent. acetic acid, not mineral acids. The ammonia is very difficult to wash away from the precipitate produced by that agent. G. Wagner made the ortho-acid by decomposing the tetrachloride with much water. The colour of the hydroxide is white, but if foreign oxides be present, the colour may be reddish, reddish-yellow, or yellow. If some nitric acid be added to the soln. of titanium tetrachloride before the aq. ammonia is added, the precipitate is white after calcination. The presence of ammonium nitrate, said O. F. von der Pfordten, prevents the formation of titanium nitride. H. Rose showed that while orthotitanic acid remains fully hydrated, it is soluble in dil. hydrochloric and sulphuric acids, and the stronger organic acids, forming the corresponding salts ; but when heated, it loses water, and forms complex, less soluble hydrates. A. Demoly said that when orthotitanic acid is dried in vacuo, it is insoluble in acids, and in that respect it resembles the meta-acid. When ignited, it forms titanium dioxide. According to V. Merz, when the hydrate has been dried 24 hrs. in air, it contains 35·43–35·70 per cent. of water ; and after drying 4–8 weeks, 29·83–31·11 per cent., thus corresponding with $Ti(OH)_4$. If the precipitate is dried 12 hrs. over conc. sulphuric acid, it contains 31·06–31·92 per cent. of water ; and a similar result was obtained by W. Delffs. After drying a week over conc. sulphuric acid, V. Merz found that the precipitate contained 28·0–28·37 per cent. of water ; after exposure for 4 weeks, 16·69 per cent. ; and after 10 weeks, 15·69 per cent. H. Rose found 12·53–16·05 per cent. water to be present after drying many weeks over sulphuric acid ; and after exposure to dry air to constant weight, A. Demoly found the composition corresponded with $3TiO_2.5H_2O$. H. Rose found that after drying in vacuo, over sulphuric acid, the composition approximated $2TiO_2.H_2O$; and J. Tuttscheff, $2TiO_2.3H_2O$. According to V. Merz, the hydrate dried at 60° corresponds with $4TiO_2.3H_2O$; and at 100°, with $2TiO_2.H_2O$. A. Demoly found 7·0 per cent. of water in the hydrate dried at 140°. T. Matsubara showed that when refined titanic acid is dehydrated at temp. exceeding 400°, it acquires a yellow tinge. C. Dreher found the ortho-acid forms lakes with some dyes, but the anhydrides, or the hydrates of the bi- or tervalent oxides, do not form lakes. The ortho-acid gives an orange-yellow coloration with tannin.

H. Rose found that **metatitanic acid,** $TiO(OH)_2$, or H_2TiO_3, is precipitated from hot soln. Thus, boiling of an aq. soln. of titanium tetrachloride is attended by the partial precipitation of the meta-acid. When washed with water, it passes through the filter-paper as a turbid liquid, and at the same time clogs up its pores. This inconvenience does not occur if the water used for the washing is mixed with an acid, alkali, or salt. The precipitation occurs more readily in the presence of a sulphate or sulphuric acid, owing to the inferior stability of titanium sulphate. The hydrolysis which occurs on boiling a slightly acid soln. of titanium sulphate is utilized in quantitative analysis. The action was discussed by A. Demoly, E. Riley, K. Bornemann and H. Schirmeister, L. Weiss and M. Landecker, H. Pellet and C. Fribourg, P. Holland, D. Forbes, J. Brakes, C. Baskerville, A. Leclerc, etc. L. Lévy showed that on boiling for 6 hrs. soln. with n grms. of free H_2SO_4 per 100 c.c. (the first soln. had a slight excess of potassium hydroxide) :

nH_2SO_4			0·000	0·000	0·000	0·083	0·500	1·000	5·766
TiO_2 {Used	.	.	0·086	0·036	0·086	0·086	0·086	0·082	0·030
{Ppd	.	.	0·108	0·100	0·047	0·036	0·085	0·080	0·000

Hence, if too much sulphuric acid be present, the titanium dioxide will be imperfectly precipitated. The precipitate is washed with hot water. The last traces of sulphuric acid are difficult to remove. V. Merz washed with an ammoniacal soln., but H. Rose, and A. Demoly found the last traces of ammonia are then difficult

to remove. H. Rose made the meta-acid by fusing a titaniferous mineral with potassium hydrosulphate, and boiling the aq. soln. of the cold mass. A. Demoly boiled a mixture of water, titanium tetrachloride, and barium carbonate, and obtained tabular crystals of the meta-acid; he also obtained the meta-acid by drying the ortho-acid in vacuo, or heating it to 140°; F. P. Dunnington made some observations on this subject. R. Weber obtained the meta-acid by the action of nitric acid, sp. gr. 1·25, on the metal. The meta-acid is a white powder which H. Rose found to be insoluble in water; almost insoluble in dil. acids; and soluble in hot conc. sulphuric acid. He observed no calorescence during the ignition of the meta-acid. V. Merz found that the meta-acid slowly loses water, and after many weeks' drying in air contained 18·48–19·22 per cent. of water; and after 24 hours' drying over conc. sulphuric acid, it contained water eq. to $TiO_2.H_2O$; and after 6 to 10 weeks' drying, $2TiO_2.H_2O$. After drying in vacuo, A. Demoly found water eq. to $3TiO_2.2H_2O$; he also found 12 per cent. of water present after drying at 140°; and J. Tuttscheff, 22·15–22·46 after drying at 120°; and 12·95 at 140°. V. Merz found that when dried at

	60°–70°	100°	120°	130°	150°	170°
Per cent. H_2O	9·45–10·91	6·83	5·17–5·46	5·05–5·53	4·22–4·46	4·17–4·53
Ratio $TiO_2 : H_2O$	—	3 : 1	4 : 1	—	—	5 : 1

C. H. Milligan and E. E. Reid found that titanic acid gel is about half as active as silica gel in promoting the esterification of alcohol. H. Rheinboldt and E. Wedekind studied the absorption of dyes by titanic acid; and A. M. Morley and J. K. Wood showed that the relatively greater surface of α-titanic acid, prepared with cold soln., gave it a greater absorptive capacity for dyes than β-titanic acid, prepared from boiling soln. Titanic acid prepared from alkaline soln. adsorbed basic but not acidic dyes; but titanic acid precipitated from slightly acid soln. adsorbs acidic but not basic dyes; while titanic acid, precipitated by calcium carbonate from soln. of titanic chloride, had a relatively low adsorptive power, but adsorbed both acidic and basic dyes. The difference in behaviour of titanic acid obtained from acid and alkaline soln., respectively, may be attributed to the amphoteric character of titanium hydroxide, resulting in the formation in the one case of a highly basic titanium salt, and in the other, of an alkali titanate; or it may be accounted for by the adsorption of hydrogen- or hydroxyl-ions, giving positively and negatively charged colloidal particles, respectively. Titanic acid, obtained by precipitation with calcium carbonate, would be neutral and have no preference for negative or positive ions of basic or acidic dyes.

The chemical properties of titanium dioxide.—O. F. von der Pfordten's [26] comparison of the properties of the three titanium oxides is shown in Table V,

TABLE V.—COMPARISON OF THE PROPERTIES OF THE TITANIUM OXIDES.

	TiO_2	Ti_2O_3	TiO
Ether reaction	—	—	Brown
Ammonia	White	Bluish-black	Black
Sod. phosphate	White	Bluish-white	Bluish-black
Sod. oxalate	White	Yellowish-brown	Greenish-brown
Sod. acetate	White	—	Greenish-black
Pot. ferrocyanide	Reddish-yellow	Brownish-red	Dark brown
Pot. ferricyanide	Yellow	Coffee-brown	Reddish-brown
Tannin	Orange	Brown	Reddish-brown

where TiO_2 is represented by a mixture of titanium chloride and alcohol diluted with water; Ti_2O_3, by the violet soln. of titanium trichloride, or the green soln. from potassium fluotitanate in hydrochloric acid; and TiO, by an aq. soln. of the dichloride. H. Rose said that **hydrogen** has no action on titanium dioxide at a

red heat. H. von Wartenberg was unable to reduce titanic oxide to the metal by hydrogen at 10 atm. press. at 2500°. H. Gall and W. Manchot found that quadrivalent titanium compounds form an equilibrium condition with tervalent titanium when heated with hydrogen in the presence of platinum. J. J. Ebelmen's and O. F. von der Pfordten's observations on the reduction of heated titanium dioxide by dry hydrogen have been discussed in connection with the lower oxides. F. Bischoff and H. Adkins measured the adsorption of hydrogen by titania. G. A. Kenngott found that powdered rutile moistened with **water** reacted alkaline. C. Doelter found rutile to be slightly soluble in water, and more so in a soln. of sodium fluoride; after heating for 34 days to 145°, the mineral partially recrystallized. For the action of **hydrogen dioxide,** *vide* titanium trioxide. L. Weiss and M. Landecker noted the accelerating influence of hydrogen dioxide on the rate of dissolution of titanium dioxide in acids, but O. Hahn and H. Gille could not confirm this; they found titanic acid is quite soluble in sulphuric acid soln. of hydrogen dioxide, and becomes less soluble in the presence of tantalic acid; they also found that the soln. is, ultramicroscopically, a true soln. According to L. Schönn, when titanium dioxide is triturated with **barium dioxide,** a deep reddish-yellow colour appears which becomes deep yellow when an acid is added. The coloration disappears by reduction with zinc, or with ferrous or stannous chloride.

According to C. Friedel and J. Guérin, when titanium dioxide is heated in a stream of **chlorine,** some titanium tetrachloride is formed and oxygen evolved; if the dioxide is mixed with carbon, carbon monoxide and the tetrachloride are formed. The affinity of titanium dioxide for acids, said H. Rose, is very feeble. The crystals of the mineral, and of the ignited oxide dissolve only in **hydrofluoric acid.** M. E. Pennington said that the ignited oxide dissolves in this acid very slowly; and if the oxide has been calcined to about 1000°, it is virtually insoluble in hydrofluoric acid; the oxide calcined at 700° soon dissolves in this acid. Soln. of titanium dioxide in various **acids** are obtained by using the hydrated oxide. H. Rose added : The dissolution is effected slowly, but the action is faster if conc. acids slightly warmed be employed than is the case with hot dil. acids. The hydrated titanium dioxide precipitated by ammonia, and washed with cold water, dissolves the most readily; that which has been washed with hot water less readily; and that obtained by boiling a dil. soln. in hydrochloric acid, least readily. L. Weiss and M. Landecker found the hydrated dioxide dissolves more quickly in **hydrochloric acid** than it does in nitric or sulphuric acid. They also state that titanium dioxide is insoluble in **perchloric acid.** H. Traube studied the etching of rutile with **potassium fluoride** or hydrofluoride. According to E. Schulze, when titanium dioxide is ignited with an **alkali chloride** in the presence of oxygen, there is a slight decomposition; and in the absence of oxygen titanium dioxide is without action on **potassium iodide.**

For the action of **sulphur,** *vide* titanium sulphides. According to H. Rose, when strongly heated in a stream of **hydrogen sulphide,** titanium dioxide is blackened, but the colour is restored when the product is calcined in air. E. F. Smith found that when heated in the vapour of **sulphur chloride,** rutile forms titanium tetrachloride. G. Darzens and F. Bourion found that a mixture of chlorine and SCl_2 vapour at a red heat forms $2TiCl_4.SCl_4$; and that with **thionyl chloride,** a similar complex is produced. According to H. Rose, when the vapour of **carbon disulphide** is passed over heated titanium dioxide, carbon monoxide and dioxide, and titanium sulphide are formed. L. Wöhler and co-workers found titanium dioxide acts as a catalytic agent in the oxidation of **sulphur dioxide** to the trioxide. Titanium dioxide in its different forms is insoluble in **sulphuric acid**; but the hot acid slowly transforms the powdered dioxide into sulphate—*vide* hydrofluoric acid. K. Bornemann and H. Schirmeister said that titanium dioxide which has been heated to 1000° is virtually insoluble in sulphuric acid; but if the temp. of ignition has not exceeded 700°, dissolution in conc. sulphuric acid occurs in 15 min. R. D. Hall and E. F. Smith found that a mixture of 40 grms. of water and 70 grms.

of sulphuric acid of sp. gr. 1·145, dissolved 0·33 grm. titanium dioxide in 15 min. M. Blondel found that rutile readily dissolves in conc. sulphuric acid when heated to about 225°, but if the temp. of the acid exceeds 225°, a layer of sulphate forms on the surface, protecting the mineral from further attack by the acid. According to L. Weiss and M. Landecker, the speed of dissolution of ignited titanium dioxide in sulphuric acid is augmented by hydrogen dioxide; they also stated that the hydrated dioxide dissolves more slowly in sulphuric acid than it does in nitric or hydrochloric acid; and K. Bornemann and H. Schirmeister, less rapidly in sulphuric acid than in hydrofluoric acid. The fusion of titanium dioxide with **potassium hydrosulphate** readily brings about the complete soln. of titanium dioxide. K. Bornemann and H. Schirmeister add that it is not necessary to dissolve the product in cold water, for if dil. sulphuric acid be used, dissolution is complete, even if the liquid is boiled. P. Müller attempted to obtain titanium alloys free from sulphur, together with volatile titanium sulphides, by smelting a mixture of carbon, rutile, and nickel sulphide or iron sulphide in the electric arc furnace. The quantities were mixed according to the equations: $TiO_2+FeS+2C=TiS+Fe$ $+2CO$ or $5TiO_2+3FeS+10C=Ti_2S_3+3(Fe,Ti)+10CO$, but it was found possible to obtain an iron-titanium alloy free from sulphur only by employing a double quantity of rutile and so large an excess of carbon that the iron and a portion of the titanium could form carbides. Similar results were obtained with nickel matte when a large excess of rutile was employed; in no case did the double carbide retain any appreciable amount of sulphur. The high current consumption is opposed to the economical application of the method, and the chief result of the investigation is to show that titanium, like silicon, acts at high temperatures as a desulphurizing agent.

According to F. Wöhler, the affinity of **nitrogen** for titanium is great enough for the two elements to unite at a high temp., forming the nitride (q.v.); but F. Wöhler and H. St. C. Deville observed that no nitride is formed at a bright red heat in a current of hydrogen and nitrogen, but the oxide assumes a greyish-black colour. F. Wöhler also found that with the dioxide at a red heat, **ammonia** forms water, hydrogen, and titanium nitride. H. Rose said that titanium dioxide is not changed when heated with ammonium chloride, but if the dioxide is associated with stannic oxide, some titanium tetrachloride is formed. For the action of **nitric acid,** vide hydrochloric acid. L. Weiss and M. Landecker found that the hydrated dioxide dissolves more slowly in nitric acid than it does in hydrochloric acid, and more quickly than in sulphuric acid. C. F. Rammelsberg found that molten **potassium nitrate** is without action on titanium dioxide. R. Weber observed that titanium dioxide is decomposed when heated in the vapour of **phosphorus pentachloride,** and J. Tuttscheff found that phosphoryl chloride and a compound, $TiCl_4.PCl_5$, is formed (q.v.). Titanium dioxide dissolves in molten **borax,** or microcosmic salt, and gives an amethyst blue in the reducing flame, and a pale blue in the oxidizing flame. The reaction was studied by J. J. Berzelius, R. Bunsen, E. Riley, G. Rose, E. J. Chapman, R. Brauns, etc. L. Weiss and M. Landecker found that a fused mixture of two parts of sodium carbonate and one of borax readily dissolves titanium dioxide.

H. Rose said that titanium dioxide is reduced to the metal by **carbon** at a white heat. According to F. Wöhler and H. St. C. Deville, when a mixture of carbon and titanium dioxide is heated in a carbon crucible, there is formed *Kohlenstoffstickstofftitan*—the nitrogen comes from the air. By heating titanium dioxide in an electric arc-furnace with carbon electrodes at 50-70 volts, and 100 amps., H. Moissan found that the blue oxide is formed; with 350 volts, the nitride is formed; with 1200 volts, the carbide is formed; with 1000 volts, the titanium has 15·3 per cent. of carbon; with 1200 volts, 11·2 per cent. of carbon. I. L. Bell found that when the dioxide is heated in a current of **carbon monoxide,** about 4·7 per cent. of oxygen was lost, and some carbon was formed. F. Göbel also studied the reaction; but H. Rose said that there is no action at a red heat. F. Bischoff and H. Adkins

studied the adsorption of **carbon dioxide** by titania. According to E. A. Demarçay, and P. Camboulives, titanium dioxide heated to about 400°–430° in the vap. of **carbon tetrachloride,** furnishes titanium tetrachloride, but, according to L. Meyer, there is no reaction if the dioxide is heated to a very high temp. Fused **alkali carbonates** react with titanium dioxide, forming titanates (*q.v.*). K. Bornemann and H. Schirmeister found that after fusion with alkali carbonate, and dissolution in hydrochloric acid, the residue is difficult to wash, and readily passes through the filter-paper; and that this is avoided by the use of sulphuric acid (1 : 2) in place of hydrochloric acid. H. Geisow said that no titanium is removed by washing with water the mass obtained by fusing alkali carbonate and titanium dioxide. The reactions of titanium dioxide and the alkali carbonates have been studied by D. P. Smith, T. Scheerer, and E. Mallard. C. F. Rammelsberg found that titanium dioxide is not attacked by **potassium cyanide.** A. Benrath found that titanium dioxide in the presence of **alcohol** or **oxalic acid** is reduced in light. P. Sabatier and A. Mailhe found that calcined titanium dioxide is reduced by the vapour of a primary alcohol at 350°–400°; and they studied the catalytic influence of titanium dioxide on the formation of **ethers,** and on the decomposition of **formic acid.** C. N. Hinshelwood and B. Topley found the heat of activation of titanic oxide in the reaction $H.COOH=CO+H_2O$ to be much greater than is the case with glass. P. Sabatier and A. Mailhe, and F. Bischoff and H. Adkins studied the catalytic action of titanic oxide in the dehydration of alcohols, etc. F. Bischoff and H. Adkins also studied the adsorption of **ethylene** and **ethane** by titania. A. Kling also studied the catalytic effect of titanium dioxide on alcohol. Titanium dioxide alone is stable towards light, but C. Renz showed that it becomes markedly *photosensitive* in the presence of certain organic liquids and reducing soln., particularly glycerol. G. Tammann found that **silicon** reacts with titanium dioxide at a high temp., forming titanium sesquioxide, and silica. L. Bourgeois studied the action of **silica** on titanium dioxide—*vide* titanium silicates—and he found that when a mixture of **stannic oxide,** silica, titanium dioxide, and calcium chloride is fused, crystals containing the dioxide are formed. According to L. Troost and P. Hautefeuille, **silicon tetrachloride** does not attack red-hot titanium dioxide, but at 360°–370°, G. Rauter found that a little titanium tetrachloride is formed.

According to H. Rose, **sodium** or **potassium** at a red heat reduces titanium dioxide. The reaction is accompanied by a moderate incandescence; and in addition to the alkali oxide, a black powder, not susceptible of metallic lustre, is formed, and the product is considered to be a mixture of the metal and its oxide. T. König and O. F. von der Pfordten observed the reduction of heated titanium dioxide by the vap. of sodium, forming TiO, Ti_2O_3, and Na_3TiO_3 (*q.v.*). A. Burger, and W. Huppertz found that titanium dioxide is reduced to the metal when heated with **calcium.** According to C. Winkler, and L. Gattermann, **magnesium** or **zinc** reacts with titanium dioxide with incandescence and partial reduction. For the reduction of the dioxide by **aluminium,** *vide* titanium. H. Baumhauer studied the etching of anatase with **potassium hydroxide;** and found that after fusion with potassium or sodium hydroxide, the mineral is dissolved by acid. The fused alkali converts the titanium dioxide into a titanate (*q.v.*).

§ 8. The Titanates

Titanium hydroxide, $Ti(OH)_4$, is amphoteric since it dissolves in the stronger acids to form salts, and in the stronger alkalies to form titanates. The *pertitanates* are described in connection with pertitanic acid—*vide infra*. H. Rose [1] showed that titanic acid is so feeble that it is unable to displace carbonic acid from aq. soln. of the carbonates at ordinary temp. E. J. Mills and D. Wilson studied the reaction between potassium carbonate and titanic oxide, at 880°, and stated that owing to the evolution of carbon dioxide, the reaction is incapable of simultaneous inversion. D. P. Smith, however, has shown that when titanic oxide is fused with alkali carbonate, the reaction is reversible in an atm. of carbon dioxide. At 900°–1100°, in an atm. of carbon dioxide at one atm. press., the conditions of equilibrium are $0.29Na_2CO_3 + 0.29TiO_2 \rightleftharpoons 0.71Na_2TiO_3 + xCO_2$; and $0.65K_2CO_3 + 0.65TiO_2 \rightleftharpoons 0.35K_2TiO_3 + xCO_2$. The power of displacing carbon dioxide from carbonates diminishes from silica, titania, zirconia, to thoria, and there is a corresponding increase in the basic power of the oxide. Expressing the solubilities in mgrms. per 100 c.c. of soln., V. Auger found the solubility of titanic oxide in a 10 per cent. soln. of *sodium hydroxide* to be 2.0–2.5; and in a 36 per cent. soln., 6–10; in a 10 per cent. soln. of *potassium hydroxide*, 30–45; and in a 40 per cent. soln., 70–90; in a sat. soln. of *potassium hydrocarbonate*, 700; a sat. soln. of *sodium carbonate* did not dissolve titanic oxide, but with a 10 per cent. soln. of *sodium hydrocarbonate*, the solubility was 25; a 30 per cent. soln. of *potassium carbonate*, 2; and a sat. soln., 30. All the titanic oxide present in the three last-named soln. was precipitated on diluting and boiling. When one part of titanic oxide is fused with 40 parts of sodium hydroxide, and the cooled melt extracted with water, the only crystalline material obtained is a hydrate of sodium hydroxide. A little titanic oxide remains in soln., the majority being precipitated even from conc. soln. Fusion of titanic oxide with potassium hydroxide, etc., affords a metastable soln. of a titanate (containing up to 1800 mg. of oxide per 100 c.c.), but this deposits most of its titanium (leaving about 100 mg. in soln.) in a few hours. Fusion of titanic oxide with sodium carbonate also gives metastable soln., containing 10–25 mg of oxide per 100 c.c., all of this being precipitated on keeping.

The titanates are quite analogous to the silicates, and the two kinds of salt are isomorphous. P. Groth emphasized how titanium dioxide replaces silica isomorphously in many minerals—*e.g.* in biotite, augite, olivine, etc.; and the oxides, zirconia, thoria, and stannic oxide, may also replace silica isomorphously. None of these oxides, however, is known to form salts of such complexity as are formed by silica. A. Rosenheim and O. Sorge made some complex organic titanates.

The old text-books refer to a salt, *ammonium titanate*, obtained by H. Rose [2] as a coherent, flocculent precipitate easily washed on the filter. It is produced by adding aq. ammonia to the milky mixture of hydrated titanium dioxide and water; or by precipitating a soln. of titanium chloride or sulphate with ammonia. It is probably colloidal titanium hydroxide with adsorbed ammonia. J. J. Berzelius found that a clear glass is obtained by fusing the right proportions of alkali carbonate and titanium dioxide. The glass devitrifies on cooling, and in so doing becomes red hot. According to H. Rose, when a mol of titanium dioxide is fused with an excess of potassium carbonate, one mol of carbon dioxide is liberated. Two liquid strata are formed—the upper layer contains an excess of potassium carbonate with but a trace of titanium dioxide, and the lower layer is normal **potassium metatitanate,** K_2TiO_3. If the fusion is arrested before the action has ceased, the carbon dioxide still evolved from the interior of the mass, forces its way through the hardening surface and renders it uneven. L. N. Vauquelin made the same compound by fusing a mixture of titanium dioxide and potassium hydroxide. As indicated above, D. P. Smith, and E. J. Mills and D. Wilson studied the equilibrium

relations between potassium carbonate and titanium dioxide. Potassium metatitanate forms a yellow fibrous mass which is more fusible than potassium carbonate. According to S. Motylewsky, the drop-weight of fused potassium metatitanate is 192 when that of water at 0° is 100 mgrms. The salt is decomposed by water into a soluble basic titanate, and an insoluble acid titanate. A. Demoly prepared **tetrahydrated potassium metatitanate,** $K_2TiO_3.4H_2O$, by boiling precipitated titanium dioxide with a soln. of potassium hydroxide; or by fusing the dioxide with an excess of potassium hydroxide, and extracting the mass with water. On evaporating the soln., colourless, prismatic crystals are produced. The salt is very hygroscopic, and readily soluble in water; the soln. has an alkaline reaction, and it gives a precipitate when treated with alcohol, or with a potassium, sodium, or ammonium salt.

According to L. N. Vauquelin, and H. Rose, hydrated titanium dioxide, and the potassium titanates are slightly soluble in an excess of potash-lye, and it is assumed that a basic titanate is formed. F. Wöhler also obtained a basic titanate by dropping a soln. of titanium tetrachloride into an excess of potash-lye; the precipitate first formed redissolves, but is reprecipitated on adding sulphuric acid. As indicated above, a soln. of a basic titanate is formed when a fused cake of titanium dioxide and potassium hydroxide is digested with water. C. F. Rammelsberg also noted that a precipitate is obtained by treatment with hydrochloric, sulphuric, nitric, or oxalic acid, and that the precipitate is soluble in excess. J. C. G. de Marignac made some observations on this subject. L. N. Vauquelin obtained a voluminous white mass of a hydrated potassium titanate by boiling titanium dioxide with potash-lye.

A. Demoly obtained an amorphous dihydrated **potassium paratrititanate,** $K_2O.3TiO_2.2H_2O$, or $K_2Ti_3O_7.2H_2O$, by adding potassium carbonate to a soln. of titanium tetrachloride. The product is insoluble in water. V. Auger could not verify the existence of this compound. H. Rose found the residue obtained by treating potassium metatitanate with cold water approximated *potassium hexatitanate*, $K_2O.6TiO_2.2(or\ 3)H_2O$; and A. Demoly obtained a similar substance by the action of conc. hydrochloric acid on the paratrititanate. The microcrystalline mass was found by H. Rose to be completely soluble in cold hydrochloric acid if it has been washed with only cold water; but after it has been dried at 100°, it is not completely soluble in that acid. The dried substance loses 14·48 per cent. of water at 100°. It is decomposed into titanium dioxide and potassium chloride when mixed with ammonium chloride and ignited. H. Rose found that if the metahexatitanate, be digested with conc. hydrochloric acid and the soln. saturated with ammonia and filtered, *potassium dodecatitanate*, $K_2O.12TiO_2$, is formed. H. Geisow prepared *enneahydrated potassium dodecatitanate*, $K_2O.12TiO_2.9H_2O$, as a white crystalline powder by melting titanium dioxide with 8-10 times its weight of potassium carbonate, washing the product with water until the runnings are free from alkali, and drying over conc. sulphuric acid. The product is not completely dehydrated at 105°. It is doubtful if these higher titanates are chemical individuals.

J. J. Berzelius, and R. Bunsen observed with sodium carbonate and titanium dioxide phenomena similar to those observed with potassium carbonate. As the cooling glass ceases to glow, the evolution of heat is so great that the mass again becomes red hot. E. Mallard reported the formation of **sodium orthotitanate,** Na_4TiO_4, by fusing sodium carbonate and titanium dioxide. H. Rose reported the formation of **sodium metatitanate,** Na_2TiO_3, by fusing a mixture of titanium dioxide with 5-12 times its weight of sodium carbonate. As with potassium carbonate, the upper layer consists mainly of sodium carbonate and the lower layer sodium metatitanate. E. Mallard made analogous observations. D. P. Smith studied the reversibility of the reaction: According to S. Motylewsky, the drop-weight of the fused salt is 216 when that of water at 0° is 100 mgrms. Sodium metatitanate is decomposed by water, sodium hydroxide passes into soln., and a hydrated acid titanate remains as a residue. A. Demoly prepared *tetrahydrated sodium metatitanate*, $Na_2TiO_3.4H_2O$, with properties like the corresponding

potassium salt; but V. Auger could not confirm this. P. J. Holmquist prepared this salt, using sodium fluoride as a flux.

P. Cormimbœuf obtained what he regarded as a *sodium sesquititanate,* $2Na_2O.3TiO_3$, *i.e* **sodium mesotrititanate,** $Na_4Ti_3O_8$, by heating for 12 hrs. five parts of sodium tungstate and a previously fused mixture of 2 parts of sodium carbonate and 1 of titanium dioxide at 800°. The milk-white, short, prismatic crystals are optically active, and belong to the monoclinic system. They are macled like the felspars. They are insoluble in water, but dissolve slowly in cold hydrochloric acid, more rapidly when heated. What P. Cormimbœuf called *sodium trititanate,* $Na_2O.3TiO_2$, *i.e.* **sodium paratrititanate,** $Na_2Ti_3O_7$, was obtained in long, highly birefringent needles by heating 10 parts of normal sodium tungstate and 5 parts of tungstic anhydride with a previously fused mixture of 2 parts of titanium dioxide and 4 parts of sodium carbonate. It is almost insoluble in boiling hydrochloric acid, and in sulphuric acid it dissolves about as readily as titanium dioxide. P. J. Holmquist obtained white, lustrous, acicular crystals of sodium paratrititanate by using sodium fluoride as a flux. The crystals belonged to the monoclinic system, and have the axial ratios $a : b : c = 1 : - : 1.2346$, and $\beta = 87° 48'$. The sp. gr. varied from 3·352 to 3·5077. The crystals have a strong double refraction like those of zircon. Boiling conc. sulphuric acid completely decomposed the salt. G. Wunder also obtained $Na_2O.3TiO_2$ by melting sodium phosphatotitanate with an excess of sodium carbonate. P. Cormimbœuf also made what he called *sodium dititanate,* $Na_2O.2TiO_2$, *i.e.* **sodium mesodititanate,** $Na_2Ti_2O_5$, in imperfect crystals of similar form by heating 20 parts of normal sodium tungstate and 5 parts of tungstic· anhydride with a previously fused and finely powdered mixture of 4 parts of titanium dioxide and 8 parts of sodium carbonate. The crystals are insoluble in water and are very slowly attacked by cold hydrochloric acid, but dissolve rapidly when heated with this acid. When the composition of the fused tungstate approaches that of the normal tungstate, rutile separates instead of a titanate. The acid titanates seem unable to take up further quantity of base, even when fused with highly basic tungstates. When P. J. Holmquist tried to make this salt he always obtained the paratrititanate.

A number of other acid titanates have been reported without evidence as to their chemical individuality. Thus, H. Rose obtained a product approximating $2Na_2O.9TiO_2.5H_2O$ by the action of water on sodium metatitanate, and afterwards washing the residue until the runnings appear milky. H. Rose also obtained a product corresponding with $Na_2O.20TiO_2$ by treating sodium metatitanate with conc. hydrochloric acid, and then with an excess of ammonia.

In 1839, G. Rose [3] described a mineral from the Urals which contained calcium and titanium oxides. He called it *perofskite,* or **perowskite,** or *perovskite,* according to the transliteration adopted for the letters of the Russian's name after whom the mineral was called. Perowskite occurs in both eruptive and metamorphic rocks. It is one of the earliest minerals formed in the basic igneous rocks. A. Stelzner found it to be particularly in evidence in melilite-basaltic rocks. It occurs also in periodotites, leucitic and nephelitic rocks, crystalline schists, pyroxenic gneiss, chloritic slate of Achmatoosk, Ural ; talcose schist of Zermatt, Switzerland ; and the crystalline limestone of Schelingen, Kaiserstuhl. Reports on its occurrence have been made by E. Hussak, O. Mügge, G. H. Williams, J. S. Diller, W. C. Brögger, F. Hessenberg, G. vom Rath, H. Rosenbusch, C. Hintze, F. Zirkel, P. von Jeremejeff, N. von Kokscharoff, F. Seneca, C. V. Pantscherschinsky, etc. Analyses were reported by H. Rose, A. Damour, A. Brun, G. Strüver, A. Sauer, F. Millosevich, S. P. Popoff, P. Hautefeuille, and L. Bourgeois. The results show that the mineral is a **calcium metatitanate,** $CaTiO_3$, with a little of the calcium replaced by ferrous iron. The mineral *knopite* of Längörsholmen, Alnö, Sweden, reported by P. J. Holmquist, is considered to be a kind of perowskite contaminated with cerium sesquioxide —*vide* rare earths.

J. J. Ebelmen synthesized perowskite by fusing titanium dioxide, lime, and potassium carbonate ; and by the action of lime on an alkaline melt containing titanium dioxide and silica.   P. Hautefeuille obtained crystals of the mineral by heating a mixture of calcium chloride, titanium dioxide, and silica to redness in a stream of moist carbon dioxide, or hydrogen chloride ; P. J. Holmquist obtained similar results by fusing mixtures of sodium and calcium carbonates, and titanium dioxide ; and L. Bourgeois, by fusing a mixture of calcium carbonate, titanium dioxide, and barium chloride.   L. Bourgeois also obtained perowskite as a separation from various magmas with the same composition as natural magmas.   G. Tammann gave 675° for the temp. of formation from its constituent oxides.

The colour of perowskite varies from pale yellow to orange-yellow, reddish-brown, and greyish-black by reflected light, and greyish-white, violet-grey, brown, red, or green in transmitted light.   There is sometimes a zonal arrangement of the colours.   The crystals may be transparent or opaque.   The crystals are cubic or pseudo-cubic.   Anhedral crystals are rare ; the euhedral crystals in rocks are generally octahedra modified by the dodecahedron and cube, but in crystalline schists the cubes are often highly modified.   Although the geometric form of the crystals is fundamentally cubic, A. Ben-Saude, C. Klein, A. des Cloizeaux, N. von Kokscharoff, F. Fouqué and A. Michel-Lévy, R. Brauns, E. Mallard, G. Tschermak, P. Groth, etc., showed that the crystals are uniformly biaxial and usually positive. H. Baumhauer showed that the corrosion figures with hydrofluoric acid or potash-lye correspond with the rhombic system.   G. R. Levi and G. Natta found the X-radiograms correspond with a central-faced cube of side 7·68 A., and containing eight molecules per unit cell.   Sections of the cubic crystals from Ural and Zermatt, cut parallel to the (100)-face, show twin lamellæ parallel to both sets of cubic edges with diagonal extinction, and the bisectrix normal to a dodecahedral face ; sections of perowskite from Tyrol show fine twin lamellæ parallel to the diagonals while the bisectrix is perpendicular to the (100)-face.   The general form and optical characters are partially explained by assuming that the crystals belong to the rhombic system and have a prismatic angle of 90° corresponding to the two pairs of cubic faces and twinned with (111), or sometimes (110), as the twinning plane.   A. des Cloizeaux called the crystals *pseudocubique,* and G. Tschermak, *mimetisch-tesseral.* H. L. Bowman gave for the axial ratios of the crystals assumed to be rhombic, $a : b : c = 1 : 1 : 0.707$ approx.   The fact that the structure differs in specimens from different localities led C. Klein to assume that the original form is cubic, and that the optical anomalies are due to secondary causes.   Boracite is closely related to perowskite in structure and optical characteristics, and with it, an increase of temp. makes the crystals optically cubic.   E. S. von Fedoroff refers to perowskite in the anomalous state at ordinary temp. as *metaperowskite.*   The cubic faces of the crystals may be striated parallel to the edges, as if composed of penetration twins of pyritohedral individuals.   The cleavage is cubic, parallel to (100), is well developed.   The twinning in the octahedral face is in the form of interpenetrated cubes.   The optic axial angle of the biaxial crystals $2V = 90°$ approximately. A. des Cloizeaux found the effect of raising the temp. to be :

|	21·5°	47°	71·5°	95·5°	121°	146·5°	170·8°
$2V$.	87° 55′	88° 22′	89° 24′	90° 36′	91° 42′	92° 28′	93° 6′

H. Rose gave for the sp. gr. 4·107 ; A. Damour, 4·037–4·059 ; A. Brun, 3·974 ; P. J. Holmquist, 3·974 ; J. J. Ebelmen, 4·10 for the artificial crystals ; and P. Haute-feuille, 4·10.   The hardness is 5–6.   G. Spezia found that when heated in a blowpipe flame fed with oxygen, perowskite melted to a yellow glass.   When heated in the oxidizing flame, a greenish bead is obtained which becomes colourless on cooling ; in the reducing flame, the bead is greyish-green when hot, and violet-blue when cold.   The mineral is entirely decomposed by boiling sulphuric acid.   Calcium metatitanate was found by P. J. Holmquist to dissolve readily in molten sodium paratrititanate at a red heat.   On cooling, needle-like crystals are formed con-

taining mixed crystals of the sodium paratrititanate and calcium metatitanate ; and the sp. gr. of the mixed crystals with 16·6 per cent. of the calcium salt is 3·490 ; with 25·5 per cent., 3·504 ; and with 32·9 per cent., 3·512. The sp. gr. of the sodium salt alone is 3·352, and of the calcium salt, 3·974.

A. Piccini prepared **barium metatitanate,** $BaTiO_3$, as an amorphous mass by the ignition of barium oxyfluotitanate. J. A. Hedvall and N. von Zweigbergk showed that a mixture of molar proportions of barium dioxide and titanic oxide evolves oxygen below 300°, and above 300°, a titanate is formed ; if the proportions are 2 : 1, a basic titanate, soluble in acetic acid, is formed. G. Tammann gave 300° for the temp. of formation from its constituent oxides. L. Bourgeois obtained **barium mesotrititanate,** $Ba_2Ti_3O_8$, by heating eq. quantities of barium carbonate and titanium dioxide using an excess of barium chloride as a flux. The cold mass was extracted with dil. hydrochloric acid, and there remained a pale yellow or yellowish-brown crystalline powder of sp. gr. 5·91. The crystals are strongly refracting. The corresponding **strontium mesotrititanate,** $Sr_2Ti_3O_8$, was obtained in an analogous manner. The crystalline powder has a feeble double refraction and a sp. gr. of 5·1. For the *barium silicotitanate—benitoite ; sodium barium silicotitanate—leucosphenite ;* and *calcium silicotitanate—sphene* or *titanite—vide* the titanium silicates.

P. Hautefeuille[4] fused a mixture of two parts of titanium dioxide, one of magnesia, and 10 of magnesium chloride for 4 hrs. at a red heat, and then extracted the cold mass with water. The crystals were washed with hot dil. acetic acid. The composition of the octahedral crystals corresponded with **magnesium orthotitanate,** Mg_2TiO_4. The sp. gr. was 3·52 ; and the hardness was greater than that of glass. The compounds are decomposed slowly by boiling nitric acid. L. Fletcher obtained rolled pebbles of a mineral from the gem-mines of Rakwana, Ceylon, and it was called **geikielite**—after A. Geikie. Analyses by A. Dick, F. Kaeppel, and T. Crook and B. M. Jones showed that geikielite is **magnesium metatitanate,** $MgTiO_3$, probably in solid soln. with a little ferrous metatitanate, and ferric oxide. P. Hautefeuille obtained crystals of magnesium metatitanate by heating white hot a mixture of one part titanium dioxide, 10 parts of magnesium chloride, and a little ammonium chloride, and extracting the cold melt with water and acetic acid. The crystals were also made by J. J. Ebelmen, C. Winkler, and L. Bourgeois. G. Tammann gave 725° for the temp. of formation from its constituent oxides. The crystals obtained by P. Hautefeuille were described as hexagonal or rhombic plates which scratch glass, and have a sp. gr. 3·91. The colour of the mineral is bluish- or brownish-black. P. Groth said that the crystals are rhombohedral, and are isomorphous with ferrous and manganous metatitanates ; and with the wollastonite obtained in slags. P. Sustschinsky gave for the axial ratio $a : c$ of the rhombohedral crystals 1 : 1·370 ; and the sp. gr. 3·976 ; A. Dick found the sp. gr. 3·98–4·00, and the hardness 6. The birefringence is high, and the optical character negative. The powdered mineral is slowly decomposed by hot hydrochloric acid ; and P. Hautefeuille said that fused ammonium hydrosulphate decomposes magnesium metatitanate. For *magnesium silicotitanate*, vide *titano-olivine.*

C. U. Shepard[5] described small, slender, prismatic crystals of a mineral which he found in the limestone of Edenville, New York, and called **warwickite ;** T. S. Hunt called the mineral *enceladite.* Analyses by J. L. Smith correspond with **magnesium borotitanate,** $6MgO.FeO.2TiO_2.3B_2O_3$, or $Mg(BO_2)_2.Mg_2TiO_4$, with part of the magnesium replaced by ferrous iron. Analyses were also made by J. E. Whitfield, who gave the formula $4RO.TiO_2.B_2O_3$; and by W. M. Bradley, who gave the formula $(Mg,Fe)_3TiB_2O_6$, or

$$\begin{array}{l} Mg{=}O_2{=}B \\ Mg{=}O_2{=}B \end{array}{>}Ti{<}\begin{array}{l} O \\ O \end{array}{>}Mg$$
The crystals are dark brown or black in colour, with a copper-red tinge on the cleavage surface. The rhombic crystals, according to A. des Cloizeaux, have the

axial ratios $a : b : c = 0.977 : 1 : —$. The (100) cleavage is perfect. A. Lacroix gave for the optic axial angle $2E = 125°$. The sp. gr. is 3·355, and the hardness 3–4. The double refraction is strong; and the optical character is negative.

When a mixture of titanium dioxide, zinc oxide, zinc sulphate, fluoride or chloride, and potassium sulphate is heated, L. Lévy [6] found that the nature of the product is determined by the temp. and by the composition of the mixture. At a dull red heat, the sesquititanate is always formed, but at higher temp. one of the other compounds is formed according to the composition of the mixture, the proportion of potassium sulphate being of great importance. It is probable that a potassium titanate is first formed, but is subsequently decomposed by the zinc salt. In fact, the zinc compounds can be obtained by the direct action of zinc sulphate on potassium titanate. He prepared **zinc orthotitanate,** Zn_2TiO_4, or, as he called it, bibasic zinc titanate, $2ZnO.TiO_2$, by heating to bright redness a mixture of 2 parts titanium dioxide, 15 parts each of zinc and potassium sulphates. It was also made by heating zinc orthodititanate with an excess of zinc sulphate or chloride. It forms black crystalline grains of sp. gr. 4·16 at 20°. It is decomposed by chlorine, but not by hydrogen; it is dissolved by hot dil. or by cold conc. acids and alkalies, and by a fused mixture of potassium nitrate and sodium carbonate. He made **zinc metatitanate,** $ZnTiO_3$, by heating to redness a mixture of titanic oxide, 2 parts; zinc sulphate, 8 parts; and potassium sulphate, 3 parts. G. Tammann gave 700° for the temperature of formation from its constituent oxides. L. Lévy found that zinc metatitanate is a pale violet substance with a conchoidal fracture and not infrequently forms silky needles; the sp. gr. at 20° is 3·17. It is decomposed by chlorine, but not by hydrogen. Boiling acids and conc. potash attack it with difficulty, but it is slightly attacked by a fused mixture of potassium nitrate and sodium carbonate, and is decomposed by fused potash. L. Lévy made **zinc orthodititanate,** $Zn_3Ti_2O_7$, or, as he called it, *zinc sesquititanate*, $3ZnO.2TiO_2$, by heating to redness a mixture of one part of titanic oxide, 5 parts of zinc sulphate, and 1·2 parts of potassium sulphate, and washing the product with dil. sulphuric acid. It forms a yellow, crystalline powder, which is not decomposed by heat. It is decomposed by chlorine or hydrogen, and slowly by warm sulphuric or nitric acid, or a mixture of sulphuric and hydrofluoric acids. It is completely dissolved by cold hydrochloric acid, and is decomposed by fused potash, but not by a mixture of potassium nitrate and sodium carbonate. L. Lévy prepared violet crystals of **zinc paratrititanate,** $ZnTi_3O_7$, contaminated with a little ferrous iron, by heating a mixture of 7 parts of titanium dioxide, 5 parts of zinc oxide, and a small quantity of zinc fluoride, or of 7 parts of titanium oxide and 30 parts of zinc fluoride, under a thin layer of potassium fluoride in a graphite crucible for an hour and a half, washing the product with water, and then treating it with conc. sulphuric acid to remove zinc oxide and titanium fluoride. With potassium chloride in place of the fluoride, the product is a greenish mass. With a mixture of potassium and sodium chlorides, the violet needles are obtained mixed with yellowish needles of potassium titanate. The crystals are insoluble in water, alcohol, and ether; they are not affected by hot dil. sulphuric, nitric, and hydrochloric acids, nor by boiling conc. soln. of alkaline hydroxides, but they are attacked with difficulty by boiling conc. sulphuric acid, and are decomposed by fusion with potassium hydroxide. They are infusible before the blowpipe, but change to a greenish mass without loss of weight; the sp. gr. at 15° is 4·92. The crystals are not attacked by hydrogen at a red heat, but they are partially volatilized in a mixture of chlorine and hydrogen chloride. When treated with acidified hydrogen dioxide, the latter acquires a characteristic yellow colour, but the decomposition is never complete. L. Lévy also reported that **zinc mesopentatitanate,** $Zn_4Ti_5O_{14}$, or, as he called it, *acid zinc titanate*, $4ZnO.5TiO_2$, is formed at a red heat from a mixture of titanium dioxide, 3 parts; zinc sulphate, 12 parts; and potassium sulphate, 1 part; the product being washed with dil. nitric acid. It forms small, pale brown, crystalline leaflets,

and the sp. gr. at 19° is 3·68. It is insoluble in all ordinary solvents, and is decomposed by chlorine, but not by hydrogen. It is not attacked by conc. acids in the cold, but is dissolved by all except hydrochloric acid when heated, and is also dissolved by fused potassium hydrogen sulphate.

No *aluminium titanate* has been reported. R. Rieke [7] measured the fusibility of mixtures of titanic oxide and alumina, and found for the softening temp., or the m.p. :

TiO_2 .	0	20	30	40	50	60	70	80	90	100%
M.p. .	2000°	1825°	1770°	1730°	1730°	1740°	1670°	1650°	1630°	1610°

H. St. C. Deville and H. Caron heated titanium dioxide with stannous oxide to a red heat, and obtained crystals resembling rutile with about 13·8 per cent. SnO_2, and 85·7 per cent. TiO_2. No definite *stannic titanate* was produced. E. Hussak and G. T. Prior described a mineral from the diamond-bearing sands of Minas Geraes, Brazil and named it **senaite**—after J. da Costa Sena. Analyses reported by E. Hussak and G. T. Prior, and E. Reitinger correspond with $(Fe,Mn,Pb)O.TiO_2$, *lead ferrous manganous metatitanate*.

The black crystals are trigonal, like those of ilmenite, and have the axial ratio $a:c=1:0·997$. Twinning about the $(11\bar{2}0)$-plane is common. No cleavage is developed. The sp. gr. is 5·301, and the hardness 6. Altered crystals have a sp. gr. as low as 4·22. The crystals are optically uniaxial; their birefringence is low ; and they are non-magnetic. T. H. Lee obtained a mineral from the Caldas region, Minas Geraes, Brazil, which he called *oliveiraite*—after F. de Paula Oliveira—and which had a composition corresponding with **zirconium titanate**, $3ZrO_2.2TiO_2.2H_2O$. The colour is greenish-yellow, and there is no distinct crystalline structure.

According to P. Berthier,[8] titanic oxide requires eight times its weight of lead oxide for dissolution and the cold mass is pale coffee-brown, opaque, and with an even, shining fracture. G. Tammann found that the temp. of formation of **lead metatitanate**, $PbTiO_3$, from its constituent oxides is 470°. P. Hautefeuille made crystals of **manganese orthotitanate**, Mn_2TiO_4, by fusing a mixture of titanium dioxide, manganese fluoride or chloride, and sodium chloride. A. Hamberg found deep blood-red crystals of a mineral at the Harstig mine, Pajsberg, Sweden, and he called it **pyrophanite**—from $\pi\hat{v}\rho$, fire ; and $\phi\alpha\nu\acute{o}\varsigma$, shining —in allusion to its red colour and brilliant lustre. Analyses show that it is **manganese metatitanate,** $MnTiO_3$, with a little silicon replacing titanium. O. Derby found pyrophanite in Minas Geraes, Brazil. L. Bourgeois synthesized the mineral by fusing a mixture of titanium dioxide and manganese chloride at a red heat. The artificial crystals were yellowish-brown, uniaxial, optically negative, hexagonal plates. A. Hamberg found the thin, tabular, rhombohedral crystals of the mineral had the axial ratio $a:c=1:1·3692$. The (0221)-cleavage is perfect, the $(10\bar{1}2)$-cleavage is less so. The basal plane has irregular striations. The corrosion figures are asymmetric. The crystals are not pleochroic.

The discovery of titanium in the black sands of Menaccan, Cornwall, by W. Gregor [9] has been described in connection with the history of titanium. The mineral was called *menaccanite*. Various spellings have been used. R. Kirwan, for example, used W. Gregor's term ; J. H. Collins wrote *manaccanite ;* R. P. Greg and W. G. Lettsom, *menacconite ;* M. H. Klaproth, *menakanite*, and also *eisenhaltige Titanerz, Titaneisen,* and *Titanosiderum ;* D. L. G. Karsten, *mänaken ;* and A. G. Werner, *Menakeisenstein.* R. J. Haüy called it *titane oxydé ferrifère.* A titaniferous iron sand from Iserwiese and Riesengebirge was called *iserin* by M. H. Klaproth, F. A. Reuss, A. Breithaupt, and A. G. Werner. J. F. L. Hausmann united menaccanite and iserin under the term *Titaneisstein.* A. G. Werner regarded iserin as *octahedral Titaneisen oxyde ;* and F. Mohs, *hexaderal Eisenerz.* The term **ilmenite** proposed by A. T. Kupffer to designate the crystals of titaniferous iron ore from Miask in the Ilmen Mts. is usually employed for the mineral ; but numerous varieties have been recognized ; they are mainly dependent on the proportions

of iron and titanium. No satisfactory external characters have been recognized, and their true relations are in many cases doubtful.

F. Mohs referred to *axotome Titaneisen* from Hofgastein, and it was analyzed by F. von Kobell, and called *kibdelophane*—from κίβδηλος, false ; and φαίνεσθαι, to appear —in allusion to its resemblance to ilmenite and titaniferous iron ore. It contains about 50 per cent. of titanium dioxide. J. L. Bournon applied the term *crichtonite*—after J. Crichton—to a mineral from Dauphiné. Its composition was determined by J. J. Berzelius, F. S. Beudant, C. C. von Leonhard, A. Lacroix, J. C. G. de Marignac, G. Rose, H. Rose, P. Tschernik, and L. Colomba ; and it has 50-53 per cent. titanium dioxide. Normal *ilmenite* has 43-50 per cent. titanium dioxide, and menaccanite, about 42 per cent. A. Breithaupt called the titaniferous iron ore from Tvedestrand, Arendal, *hystatite*. It contained 25-33 per cent. titanium dioxide. A similar mineral was called *washingtonite* by C. U. Shepard. It was examined by J. C. G. de Marignac, and J. D. Dana. The *titanoferrite* of E. J. Chapman and the *mohsite* of A. Lévy are closely related to these minerals ; but their nature is unknown. J. D. Dana's *uddevallite* from Uddevalla, Sweden, and the titaniferous iron ore from Aschaffenberg have about 17 per cent. of titanium dioxide, and 70 per cent. of ferric oxide. The *Eisenrosen* of St. Gotthard was called *basanomelane* —from βάσανος, a touchstone ; and μέλας, black—by F. von Kobell ; it has 10-13 per cent. of titanium dioxide and is usually regarded as a titaniferous hæmatite. It was examined by G. B. Hogenraad. The hæmatite of Kragerö has about 5 per cent. of titanium dioxide. The so-called magnesium *menaccanite*, or the *picrotitanite*—from πίκρος, bitter, in allusion to the contained magnesia—of J. D. Dana, or the *picro-ilmenite* of P. Groth, contains 10-15 per cent. of magnesia. Samples were analyzed by H. W. Foote, T. Crook and B. M. Jones, etc. A partially altered variety of ilmenite from Smäland, Sweden, was named *hydro-ilmenite* by C. W. Blomstrand. The *paracolumbite* and *parailmenite* of C. U. Shepard, and the *haplotypite* of A. Breithaupt are varieties of ilmenite. A. Gavelin described black grains of a mineral he called **högbomite** in the Ruoutevare district of Swedish Lapland. It may occur in trigonal crystals with the axial ratio $a : c = 1 : 1 \cdot 55$; the sp. gr. is 3·81 ; the hardness, 6½ ; and the indices of refraction, $\omega = 1 \cdot 853$, and $\epsilon = 1 \cdot 803$. The analyses approximate $MgO.2(Al_2O_3.Fe_2O_3.TiO_2)$. T. L. Watson described a sample from Whittles, Pennsylvania, with $\omega = 1 \cdot 848$ and $\epsilon = 1 \cdot 817$.

Numerous analyses of the different varieties of ilmenite have been reported.[10] The earlier analyses have been previously indicated in connection with the discovery of the metal and of the mineral. A. Lévy,[11] and G. Rose showed that ilmenite is closely related with many of the different forms of titaniferous iron ore ; and the latter found that, although hæmatite and ilmenite have *die gleiche Krystallform*, they are not isomorphous because the constituents of ilmenite—FeO and TiO_2—are not isomorphous with ferric oxide. C. G. Mosander, however, regarded ilmenite as an isomorphous mixture of ferrous metatitanate and ferric oxide, and proved that the ferrous oxide of ilmenite can be replaced with magnesium, calcium, and manganese (ous) oxides. G. von Hevesy and V. T. Jentzen found no hafnia in the ilmenite examined by them. H. Rose said that " there can be no isomorphism between the two compounds since one is a salt derived from two oxides, and the other is a simple oxide." He assumed that ilmenite is really a mixture of Ti_2O_3 and Fe_2O_3 such that the composition $Fe_2O_3 + Ti_2O_3$ is eq. to $2FeTiO_3$. T. Scheerer, indeed, said that the blue colour developed when ilmenite is boiled with sulphuric acid favours the hypothesis that Ti_2O_3 is present in the mineral. According to E. Glatzel, the soln. contains some titanium, but T. König and O. F. von der Pfordten could find none. The last-named showed that ferric oxide and titanium sesquioxide can coexist in the same soln., so that probably no change of these oxides into titanium dioxide and ferrous oxide, as assumed by P. Groth, occurs when the mineral is treated with hot sulphuric acid. They found it to be impossible to prove in a chemical way that titanium sesquioxide exists in ilmenite. W. Manchot argued that because no hydrogen is developed when ilmenite is heated with alkali-lye or with hydrochloric or sulphuric acid, it is probable that no titanium sesquioxide is present. The mineral behaves chemically like ferrous oxide associated with titanium dioxide. J. J. Berzelius, and R. Hermann opposed H. Rose's assumptions because the magnetic properties of ilmenite indicate the presence of ferrous iron. C. F. Rammelsberg said that the constant presence of magnesium in ilmenite makes it probable that ferrous iron

is also present; especially is this so in cases where the proportion of magnesium is high. He favoured C. G. Mosander's but not H. Rose's hypothesis. S. L. Penfield and H. W. Foote confirmed C. F. Rammelsberg's conclusions. C. Friedel and J. Guérin concluded that Fe_2O_3, $FeTiO_3$, and Ti_2O_3 are isomorphous, and that the titaniferous irons are mixtures of the first two, namely, $Fe.FeO_3$ and $Fe.TiO_3$. A. Hamberg also considered that the discovery of pyrophanite supported C. G. Mosander's hypothesis, and added that there is no need to assume that ferric oxide contains quadrivalent iron $Fe^{II}.Fe^{IV}O_3$, since the case of potassium nitrate and calcium carbonate as well as other cases indicated in connection with isomorphism—1. 11, 10—show that valency is not necessarily involved in the similarity of crystalline form. To summarize, the facts favour the assumption that normal ilmenite is **ferrous metatitanate,** $FeTiO_3$, and that in the ferruginous varieties the metatitanate is isomorphously associated with ferric oxide ; and that the ferrous metatitanate may also be associated in a somewhat similar manner with magnesium, calcium, and manganous metatitanates. G. Tammann found the temp. of formation from its constituent oxides is 700°.

Ilmenite is fairly widely diffused in nature ; it is a common constituent of igneous rocks, and appears to have been one of the earliest minerals to separate from the molten magma. It occurs associated with hæmatite in granites, syenites, diorites, diabases, gabbros, basalts, and other eruptive rocks. It also occurs associated with magnetite. Ilmenite often forms inclusions in the felspar and pyroxene of gabbros and other basic rocks. It also occurs similarly in gneiss, mica-schist, and amphibolites. G. Rose [12] melted ilmenite with borax in the blowpipe flame and found hexagonal plates embedded in the cold glass. These were isolated by treatment with nitric acid, and were shown to be titaniferous iron oxide. L. Bourgeois synthesized the mineral by melting a mixture of ferrous chloride and titanium dioxide at a red heat. J. Morozewicz in his study of artificial magmas reported crystals of ilmenite in those of the basalt type. W. Bruhns obtained crystals of hexagonal plates of ilmenite, mixed with magnetite, by heating a mixture of finely divided iron, ferric oxide, titanium dioxide, and hydrofluoric acid in a platinum tube at 270°–300° for 24 hrs.

The colour of the opaque crystals of ilmenite is iron-black. The crystals are tetartohedral belonging to the trigonal system, and, according to N. von Kokscharoff,[13] have the axial ratio $a : c = 1 : 1.38458$; and, according to G. Boeris, $1 : 1.38235$. P. Sustschinsky found for specimens with different proportions of titanium dioxide :

Per cent. TiO_2 .	5·665	21·576	47·679	49·684	57·23
$a : c$ . . .	1 : 1·3680	1 : 1·3716	1 : 1·3772	1 : 3790	1 : 3844
Sp. gr. . .	5·041	4·910	4·852	4·614	—

The isomorphism of ilmenite with hæmatite is discussed above. Observations on the crystals were made by E. Artini, G. Doby and G. Melczer, M. Bauer, A. Sadebeck, O. Mügge, A. Streng, F. Sandberger, M. Websky, G. Rose, H. Bücking, R. H. Solly, G. Boeris, F. Zambonini, A. Lacroix, A. des Cloizeaux, W. H. Miller, P. von Jeremejeff, H. Smith, etc. The habit of the euhedral crystals is usually tabular parallel to (0001), and with a six-sided outline, and, often like hæmatite, elongated to blade-like shapes, less frequently in steep rhombohedral forms. The anhedral crystals may be rounded or irregularly outlined ; and sometimes in skeleton-like aggregates. Ilmenite also occurs massive and compact ; and granular —embedded or sandy. The cleavage is not developed. The twinning is like that of hæmatite, being lamellar, parallel to (0001) or (10$\bar{1}$1). Parting parallel to the twinning planes is often shown in partly altered crystals. The X-radiograms of the hexagonal crystals were studied by P. F. Kerr.

The sp. gr. given by F. von Kobell was 4·78 ; by A. Breithaupt, 5·069–5·117 ; C. F. Rammelsberg, 5·060 ; and F. Pisani, 4·353. Most of the samples analyzed had their sp. gr. determined ; and, as found by G. Doby and G. Melczer, the results

show that the sp. gr. increases up to 5·3 with the proportion of ferric oxide. P. Sustschinsky's observations on this subject are indicated above. G. A. Kenngott found the sp. gr. of ilmenite to be 4·741–4·767, and after ignition, 4·833–4·857. The hardness is 5 to 6. E. Madelung and R. Fuchs found the coeff. of compressibility of ilmenite to be $3·25 \times 10^{-12}$ dynes per sq. cm.; and of titaniferous iron ore, $2·92 \times 10^{-12}$ dynes per sq. cm. The mineral is infusible before the blowpipe; but if the blowpipe be fed with warm air, G. Spezia found that it could be melted to a black mass. A. Brun also made observations on the action of the oxy-hydrogen flame. R. Lorenz and W. Herz studied the relation between the m.p. and the critical temp. F. Zirkel said the birefringence is strong, and that the mineral is distinctly pleochroic. A. de Gramont investigated the spark spectrum. F. Beijerinck said the mineral is a good conductor of electricity, and that the conductivity increases as the temp. rises. G. Cesaro made a similar observation, and J. Königsberger and K. Schilling found that the absolute resistance of α-ilmenite falls from 2,100,000 ohms at −188° to 218·7 at 18°, and to 9·0 ohms at 200°. There is a slow conversion into β-ilmenite at about 215° when the electrical resistance falls from 1·00 ohm at 215° to 0·085 ohm at 890° (Fig. 8). The electrical resistance parallel to the c-axis is rather greater than when measured vertical to that axis. E. T. Wherry found ilmenite to be a poor radio-detector. Ilmenite slightly influences the magnetic needle. B. Bavink studied the magnetic properties. E. Zalinsky found that finely powdered ilmenite dissolves slowly when boiled with conc. hydrochloric acid; and it was completely dissolved by hydrofluoric acid after 70 hrs.' action. The soln. deposited a white powder of ferric

FIG. 8.—The Electrical Resistance of Ilmenite at Different Temperatures.

fluoride. Fused potassium hydrosulphate decomposes ilmenite and enables it to be dissolved in acid. For the action of sulphuric acid, vide supra. H. Lotz studied the action of air containing sulphur dioxide on titaniferous iron ore. For delorenzite—ferrous uranium yttrium metatitanate— and yttrocrasite—thorium yttrium metatitanate—vide rare earth minerals, 4. 38, 2. C. G. Mosander described a ferrosi-titanate, $(FeO)_3(Fe_2O_3)_4 TiO_2$, or $Fe_{11}TiO_{17}$; and P. Groth, a titanomagnetite, $\{Fe(Fe,Ti)O_2\}_2$.

P. Hautefeuille [14] reported the formation of dark purple, rhombic, prismatic crystals of ferrous orthotitanate, Fe_2TiO_4, by the fusion of a mixture of titanium dioxide, a ferrous salt, and sodium chloride. A. Koch described a mineral from Aranyer Berg, Transylvania—which was regarded as a dimorphous modification of ilmenite, and called pseudobrookite. Analyses were reported by A. Koch, G. Lattermann, A. Cederström, H. Traube, and A. Frenzel. The analyses of A. Cederström, A. Frenzel, and H. Traube agree with $2Fe_2O_3.3TiO_2$, or, in agreement with P. Groth, ferric orthotitanate, $Fe_4(TiO_4)_3$; G. Lattermann gave $(FeO)_9 Fe'''_5 Mg(TiO_3)_{13}$. B. Doss' furnace product was called pseudobrookite, but its composition corresponded with Fe_2TiO_5. The mineral has been found in a few other localities. T. König and O. F. von der Pfordten found that ferric orthotitanate, $Fe_4(TiO_4)_3$, is produced by heating a mixture of titanium dioxide, anhydrous ferrous fluoride, and a large proportion of sodium chloride. Contrary to P. Hautefeuille, they found that ferrous orthotitanate is not formed under these conditions. On ignition in hydrogen, ferric orthotitanate behaves like titanic iron ore, and is converted into iron and titanium dioxide. When warmed with conc. sulphuric acid, it turns green, and on diluting, the whole dissolves; the soln. contains titanium dioxide and ferric sulphate, but no ferrous salt. A. Koch said that the dark brown or black crystals of pseudobrookite are tabular parallel to (100), and
often prismatic. The (100)-faces may be striated horizontally. The crystals are rhombic with the axial ratios $a : b : c = 0.87776 : 1 : 0.88475$. The (001)-cleavage is distinct. A. Cederström gave 4·390, and A. Koch 4·98, for the sp. gr. The hardness is 6. The optic axial angle found by G. Lattermann is $2H = 84° 30'$. The optical character is positive. J. Königsberger and K. Schilling found a break in the electrical conductivity-temp. curve, and consequently inferred the existence of α-*pseudobrookite* and β-*pseudobrookite*. Pseudobrookite is attacked by acids with great difficulty. B. Doss found it is dissolved completely by dil. hydrofluoric acid, but the action is very slow. G. Lattermann said that boiling sulphuric acid leads to the separation of a greenish-white, crystalline powder soluble in hydrochloric acid. Pseudobrookite is completely dissolved by a mixture of sulphuric and hydrofluoric acids (2 : 1), by a mixture of sulphuric and hydrochloric acids, and by fused potassium hydrosulphate. B. Doss reported the formation of crystals of pseudobrookite in the firebricks of a soda-works at Schönebeck; and assumed that it was formed by the interaction of ferric and titanic chlorides; $TiCl_4 + 2FeCl_3 + 5H_2O = Fe'''_2TiO_5 + 10HCl$. The formula here assigned by B. Doss, is based on an analysis of the crystals, and corresponds with *ferryl metatitanate*, $(Fe'''O)_2TiO_3$.

C. Palmer found a dark steel-grey mineral associated with gadolinite at Hackberry, Arizona, and he called it **arizonite.** Analyses correspond with **ferric metatitanate,** $Fe_2(TiO_3)_3$. C. Palmer suggested that the so-called iserin is really a mixture of ilmenite and arizonite; and that Brazilian titaniferous iron sand, analyzed by J. Mackintosh, is impure arizonite. The crystals are considered to be monoclinic with the axial ratios $a : b : c = 1.88 : 1 : 2.3$, and $\beta = 55°$. The sp. gr. is 4·25; the hardness is 5·5; and the index of refraction over 1·84. The mineral is feebly pleochroic; and it is completely decomposed by hot conc. sulphuric acid. E. Rinmann reported dark brown *kalkowskite*—named after L. Kalkowsky—to occur at Serra do Itacolumy, Minas Geraes, Brazil. The analysis agrees with $(Fe,Ce)_2O_3.4(Ti,Si)O_2$. Its sp. gr. is 4·01; hardness, 3 to 4; index of refraction, over 1·769; and it is non-pleochroic. The mineral is partially decomposed by hydrochloric acid, this is also the case with arizonite; and, added W. F. Foshag, if the silica found is foreign, the kalkowskite is not essentially different from arizonite. L. Bourgeois [15] melted cobalt chloride with titanium dioxide and obtained **cobalt metatitanate,** $CoTiO_3$; and **nickel metatitanate,** $NiTiO_3$, was obtained in a similar way.

§ 9. The Higher Oxides of Titanium—Pertitanates and Hypertitanates

H. Schönn,[1] and A. Weller showed that if hydrogen dioxide be added to a soln. of titanium sulphate, an orange-yellow colour is developed. The intensity of the colour depends on the proportion of titanium in soln. The phenomenon is employed for the colorimetric determination of titanium, a process discussed by C. Baskerville, J. Brakes, H. M. Ullmann and J. W. Boyer, A. Gautier, G. P. Pamfil, T. B. Osborne, W. F. Hillebrand, J. H. Walton, G. Steiger, J. Bruhat and H. Dubois, H. E. Merwin, E. Jackson, L. Lévy, C. Reichard, etc. The coloration is affected by the presence of fluorine, phosphoric acid, and potassium sulphate. According to A. Weller, if freshly precipitated titanium hydroxide be treated with neutral hydrogen dioxide, or if a soln. of titanium sulphate be treated with hydrogen dioxide and then with aq. ammonia, a yellow substance is obtained which, when dried over conc. sulphuric acid, furnishes a yellow horny mass. Analyses show the ratio $TiO_2 : O = 1 : 0.75$ to 0.81 ; and when heated it gives off oxygen and water, forming titanium dioxide. It is therefore assumed that the product is a more or less decomposed **hydrated titanium trioxide,** or **pertitanic acid,** $TiO_3.nH_2O$. It dissolves in acids, forming a reddish-yellow soln. ; the sulphuric acid soln. is fairly stable, but the hydrochloric acid soln. soon gives off chlorine. Ether is without action ; and reducing agents decolorize the liquid. A. Classen isolated the oxide as follows :

Titanium tetrachloride was added drop by drop to dil. alcohol, and the clear, very dil. soln. was treated with a large excess of hydrogen dioxide. Ammonia, ammonium carbonate, or aq. potassium hydroxide was added to the soln., and in the case of ammonia a yellow, and in the other cases, a reddish-yellow liquid was formed, which, after some time, gave a yellow precipitate. This was repeatedly washed by decantation, and dried on a porous plate.

A. Classen's analysis corresponded with $TiO_3.3H_2O$, or $Ti(OH)_6$. A. Piccini treated a soln. of titanium sulphate with barium hydroxide, and then with hydrogen dioxide. The yellow precipitate obtained on adding potassium hydroxide never contained more oxygen than corresponded with $TiO_2 : O = 2 : 1$; the soln., however, contained the eq. of $TiO_2.H_2O_2$ and free hydrogen dioxide, but it could not be demonstrated whether a true peroxide is formed or simply the addition product $TiO_2.H_2O_2$. L. Lévy attributed the discordant results of the analyses of the product of the action of hydrogen dioxide on titanium dioxide to the slowness of the reaction, and to the decomposition of the precipitate during desiccation. He mixed a soln. of hydrogen dioxide of known conc. with definite quantities of a soln. of titanium sulphate, and after standing a long time, he showed that any

one of the three formulæ, TiO_3, $TiO_2.H_2O_2$, and $Ti_2O_5.H_2O_2$, agrees with the results. The composition of the higher chloride, and the existence of additive compounds of the oxyfluoride and alkali fluorides, afford additional evidence in favour of the formula TiO_3. P. Faber, and P. G. Melikoff and L. Pissarjewsky assume that during the action of hydrogen dioxide on soln. of salts of quadrivalent titanium, the titanium becomes sexivalent, but this is not in harmony with the position of titanium in the periodic table. If titanium be quadrivalent, hydrated titanium trioxide can be formulated :

$$(HO)_2 = Ti <^{O}_{O} \qquad \text{or} \qquad Ti <^{O.OH}_{(OH)_3}$$
P. G. Melikoff and L. Pissarjewsky found that titanium trioxide has acidic properties, and unites with the alkali peroxides in the presence of hydrogen dioxide, forming hypertitanates, or salts of the unknown anhydride, *titanium heptoxide*, Ti_2O_7. O. and A. Dony-Hénault studied the conc. of hydrogen dioxide in soln. of titanium salts required before the hydrogen dioxide is able to affect photographic plates. On the assumption that the titanium oxide must be sat. with hydrogen dioxide, before the dioxide is free to affect the plate, they inferred that the compound $TiO_2.H_2O_2$ is stable in sulphuric acid soln.

P. Faber represents the phosphate with sexivalent titanium, thus, $(HO)_3Ti \equiv O_3 \equiv P = O$. Pertitanic acid behaves like hydrogen dioxide, but is not quite so energetic. In the presence of organic reducing agents, such as formic or oxalic acid, hydrogen dioxide cannot be detected. by the chromic acid—ether reaction—but is shown readily by the titanic acid test. The conversion of the quadrivalent titanium into the sexivalent state is due to a combination with the hydroxyl groups of the hydrogen peroxide. There exists an acetate of the sexavalent titanium which is stable at low temperatures. It has a yellow colour and is insoluble in acetic acid, but soluble in mineral acids and also in alkalies and ammonia. On heating, it shows decidedly explosive properties. M. Billy considers that the supposed salts of titanium trioxide are really complexes of hydrogen dioxide and pertitanic acid corresponding with *titanium pentoxide*, Ti_2O_5 ; and a hydrated compound, $Ti_2O_5.nH_2O$, was obtained by precipitation with alcohol from a soln. prepared by pouring equimolar proportions of potassium and titanyl sulphates into an excess of hydrogen dioxide. According to A. Classen, sulphuric acid soln. gives with potassium fluoride a white precipitate of potassium fluotitanate, and liberates hydrogen dioxide ; iodine separates from potassium iodide, and ferrous salts are oxidized. The strongly oxidizing properties of the soln. resemble those of soln. of hydrogen dioxide ; *e.g.* lead and manganese dioxides are reduced. A. Mazzucchelli and C. Barbero found that unlike hydrogen dioxide, the soln. gives a red precipitate with potassium ferrocyanide, a white precipitate with acetaldehyde, and a yellow precipitate with acetone. Chromic acid is not oxidized to perchromic acid by the soln. of titanium trioxide. L. Lévy found titanium trioxide, like hydrogen dioxide, decolorizes phenolphthalein, so that if an acid soln. of titanium dioxide be titrated after the addition of hydrogen dioxide, its acidity appears to be increased. L. Weiss and M. Landecker studied the reducing action of hydroxylamine, and of sulphur dioxide. A. Mazzucchelli and C. Barbero measured the electrolytic potential of titanium trioxide in the combination $Hg \mid HgSO_4$, $N\text{-}H_2SO_4$, $Ti(SO_4)_2$, $H_2O_2 \mid Pt$, and found it to be the same as that of hydrogen dioxide. This corresponds with the existence of the compound $TiO_2.H_2O_2$ in soln. ; but it is possible that the reaction was completed before the potential was measured.

The aq. soln. of titanium trioxide may be considered to contain pertitanic acid, although it does not show an acid reaction towards indicators. The freshly precipitated trioxide is soluble in alkali-lye, and the soln. furnishes precipitates with alkaline soln. of copper, zinc, lead, and cobalt salts. No salts have been made which can be regarded as derivatives of pertitanic acid with hydrogen replaced by
a metal. P. G. Melikoff and L. Pissarjewsky prepared a number of compounds which they considered to be complex salts of pertitanic acid, and a metal hydroperoxide.

There are two series of salts : (i) *Yellow*.—The method of preparation of the yellow salts is to add well-cooled hydrogen dioxide to hydrated titanium trioxide, and then sufficient well-cooled alkali-lye to dissolve all the solid. The addition of alcohol gives a precipitate which is washed with alcohol and ether, and dried on a porous plate. Glistening yellow prisms of **ammonium peroxypertitanate,** $(NH_4)_2O_2.TiO_3.H_2O_2$, or $(NH_4O_2)_2.TiO_2.H_2O$, were so obtained. The dry salt is fairly stable, but it rapidly decomposes in soln. When heated over a free flame it gives a feeble explosion. The yellow oil first obtained with sodium compounds slowly crystallizes, forming a yellow powder of **sodium peroxypertitanate,** $Na_2O_2.TiO_3.3H_2O$. J. H. Walton made sodium peroxypertitanate from titanium dioxide and sodium dioxide. W. G. Mixter found the heat of formation of sodium peroxypertitanate to be 629 Cals. Assuming that the constitution of pertitanic acid is $(HO)_2Ti{<}^O_O$, since the soln. has all the characteristics of a peroxide, these two salts can be represented constitutionally :

$$\frac{NaO.O}{NaO}{>}Ti{<}^O_O, 3H_2O$$
Sodium peroxypertitanate.

$$\frac{NH_4O.O}{NH_4O.O}{>}Ti{<}^O_O, H_2O$$
Ammonium peroxypertitanate.
The sodium salt can also be represented as a double compound of a pertitanate with hydrogen dioxide, namely, $(NaO)_2TiO_2.H_2O_2.2H_2O$; but this formulation is considered to be less probable than the other. By double decomposition with barium chloride, sparingly soluble **barium peroxypertitanate,** $BaO_2.TiO_3.5H_2O$, is obtained as a yellow, indefinitely crystalline powder. When these compounds are treated with dil. sulphuric acid, hydrogen dioxide is formed, which is not the case with pertitanic acid alone. With hydrochloric acid, some chlorine is evolved.

(ii) *Colourless*.—Another series of compounds is obtained by a process like that just described except that larger proportions of hydrogen dioxide and of alkali-lye are used ; the alkali-lye is added until the yellow soln. becomes colourless. The small, colourless prisms of **sodium peroxyhypertitanate,** $(Na_2O_2)_4.Ti_2O_7.10H_2O$, decompose with the evolution of oxygen when dissolved in water ; and the salt does not liberate iodine from potassium iodide. It undergoes no change during several hours' exposure to air. When confined over sulphuric acid, it loses water and oxygen. Minute crystals of **potassium hyperoxypertitanate,** $K_2O_4.K_2O_2.TiO_3.10H_2O$, were formed in a similar way. The salt is stable at 0°, but deliquesces at ordinary temp. at the same time losing oxygen, and acquiring a yellow colour. The constitution is represented graphically :

$$\frac{KO.O}{KO}{>}Ti{<}^O_O, K_2O_4.10H_2O$$
Potassium hyperoxypertitanate.

$$\frac{(NaO.O)_3}{NaO}{>}Ti.O.Ti{<}^{(NaO.O)_3}_{ONa}, 10H_2O$$
Sodium peroxyhypertitanate.

but the evidence is not convincing. M. Billy made orange or yellow crystals of *potassium pertitanic sulphate* by mixing hydrated titanic acid, potassium carbonate and hydrogen dioxide. The salt readily decomposed giving off oxygen.

§ 10. Titanium Fluorides

According to P. Hautefeuille,[1] when potassium fluotitanate, K_2TiF_6, is strongly heated in a stream of hydrogen mixed with a little hydrogen chloride, dark violet prismatic crystals are formed. At first, these crystals were considered to be *titanium difluoride*, TiF_2; but later P. Hautefeuille showed that **titanium trifluoride,** TiF_3, is formed. R. Weber also made the same salt by using a current of hydrogen only. P. Hautefeuille found that purple-red titanium fluoride crystallized from molten potassium chloride is readily soluble in water, while the violet product dissolves with difficulty. R. Weber found that the trifluoride could not be separated from the alkali fluoride, and that by the prolonged action of boiling water the trifluoride decomposes, forming with the alkali fluoride, potassium fluotitanate. V. Merz dissolved titanium in 27 per cent. hydrofluoric acid, and obtained a soln. which he supposed contained titanous fluoride. C. F. Rammelsberg obtained a soln. of titanium trifluoride by reducing a soln. of potassium fluotitanate with zinc and hydrochloric acid; and O. F. von der Pfordten used sodium amalgam as a reducing agent. C. Friedel and J. Guérin made some observations on this subject.

A number of complex fluorides, **fluotitanites,** have been obtained by the union of the metal fluorides with titanium trifluoride. These salts are derivatives of **fluotitanous acid,** $HTiF_4$, but the acid itself has not been isolated. A. Piccini obtained a violet precipitate of **ammonium pentafluotitanite,** $(NH_4)_2TiF_5$, by pouring a conc. soln. of ammonium fluoride into one of titanium trifluoride; if the sequence be reversed, and the latter soln. be poured into the former, **ammonium hexafluotitanate,** $(NH_4)_3TiF_6$, is formed. The better mode of preparing the latter salt is to reduce a soln. of a fluotitanate and ammonium fluoride by electrolysis. E. Petersen made it by reducing a soln. of potassium fluotitanate with cadmium and hydrochloric acid, and then adding the product to a soln. of ammonium fluoride. The crystalline violet precipitate is slightly soluble in water, but insoluble in a soln. of ammonium fluoride. If the precipitate be washed successively with water, a conc. soln. of ammonium fluoride, and conc. alcohol, and exposed to the air, its violet colour changes to dirty yellow, and when perfectly dry, it has a deep yellow colour, and ammonium fluoroxypertitanate is formed. According to E. Petersen, the salt $(NH_4)_3TiF_6$ is isomorphous with the corresponding salts of chromium, vanadium, and iron—$(NH_4)_3CrF_6$, $(NH_4)_3VF_6$, and $(NH_4)_3FeF_6$. A. Piccini made **potassium pentafluotitanite,** K_2TiF_5, as a deep violet precipitate by adding potassium hydrofluoride to the liquid obtained by treating titanium trifluoride with water. The salt is sparingly soluble in water, for, at 21°, 100 parts of water dissolve 1·27 parts of salt. The salt is readily dissolved by dil. acids, forming green soln. which give an azure-blue precipitate with aq. ammonia or potassium hydroxide, and gradually form titanic acid on exposure to air. Potassium permanganate is decolorized by a soln. of the salt.

O. Unverdorben[2] distilled titanium dioxide in a leaden retort with fluorspar and sulphuric acid; unlike the corresponding experiment with silicon dioxide, no gas is evolved, but after a time, yellow oily drops appear which were considered to be titanium fluoride. The product is decomposed by water with the separation of titanic acid, or titanium oxyfluoride. If a glass retort be used,
it was said that a mixture of gaseous silicon tetrafluoride mixed with titanium tetrafluoride passes over. It is, however, very doubtful if the yellow oily liquid is really **titanium tetrafluoride,** TiF_4, because O. Ruff and R. Ipsen could not make the tetrafluoride by this process. H. Moissan obtained this compound by the direct union of the elements. O. Ruff and R. Ipsen said that, if gently warmed, titanium reacts with fluorine with incandescence, forming a white sublimate of titanium tetrafluoride contaminated with particles of the metal. E. Glatzel said that an aq. soln. of titanium tetrafluoride is obtained by dissolving titanium in hydrofluoric acid. O. Ruff and R. Ipsen could not make the tetrafluoride in this way; nor could they obtain it by roasting hydrofluotitanic acid with sulphuric acid. They did obtain titanium tetrafluoride by the action of anhydrous hydrogen fluoride on red-hot titanium; part of any carbon associated with the titanium remains, and part is converted into acetylene. The hydrogen fluoride should be obtained from potassium hydrofluoride, for, if obtained from calcium fluoride and sulphuric acid, the product is contaminated with titanium oxyfluoride. They recommended preparing this compound by passing thoroughly dried hydrogen fluoride over titanium tetrachloride: $TiCl_4 + 4HF = TiF_4 + 4HCl$. The yield is 90 per cent. The reaction takes place at ordinary temp.; if the temp. be raised to 100°–120°, the reaction is very fast. At ordinary temp., a layer of titanium tetrafluoride is formed over the surface of the tetrachloride, and this slackens the speed of the reaction. O. Ruff and co-workers recommended using pieces of coke soaked in the tetrachloride. The reaction between antimony tetrafluoride and titanium tetrachloride was found by O. Ruff and H. Graf to yield titanium tetrafluoride. According to J. J. Berzelius, when hydrofluotitanic acid is evaporated at a gentle heat, a syrupy liquid is obtained which furnishes crystals of titanium tetrafluoride. J. C. G. de Marignac obtained the impure tetrafluoride by igniting magnesium fluotitanate; and F. Emich, by igniting barium fluotitanate.

Titanium tetrafluoride is a white solid at ordinary temp. O. Ruff and W. Plato gave 2·833 for the sp. gr. at 11°, and 2·798 at 20·5°; the mol. vol. is 45·8; and the vap. density at 444° is 129·7–129·8 when the value calculated for TiF_4 is 124·1. The b.p. is 284°; and, according to O. Ruff and R. Ipsen, the compound sublimes over 400°. The b.p. of the tetrafluoride is higher than that of the chloride, 136°; this is in marked contrast with the corresponding salts of silicon, and the corresponding halides of other non-metals and metalloids. It thus relates titanium with the metals, and is possibly to be interpreted to mean that titanium tetrafluoride is polymerized near its b.p.
The saline nature of the tetrafluoride is emphasized by its hygroscopicity, and by its forming a clear soln. with water, which, on evaporation, deposits crystals of **dihydrated titanium tetrafluoride,** $TiF_4.2H_2O$. J. J. Berzelius said that the white powder deposited from aq. soln. of titanium tetrafluoride possibly contains *titanium oxyfluoride,* $TiOF_2$, because the fluorine is not all expelled even at a red heat. It can be driven off by ignition with ammonium carbonate. For the double salt $TiOF_2.BaF_2$, *vide infra.* Titanium tetrafluoride dissolves in conc. hydrofluoric acid, but no direct combination has been detected; the hydrogen fluoride is given off at 25°. The vapour of iodine has a slight action. Indirectly a combination does occur, and hydrofluotitanic acid is formed which furnishes a series of salts—the fluotitanates. At ordinary temp., hydrogen sulphide has no appreciable action on the tetrafluoride, but at a red heat titanium disulphide and hydrogen fluoride are formed. No action was observed with sulphur chloride, SCl_2; thionyl chloride, $SOCl_2$; sulphuryl chloride, SO_2Cl_2; and sulphur trioxide. When the tetrafluoride is heated with conc. sulphuric acid, titanium dioxide is formed; and, consequently, the tetrafluoride is not produced by heating a mixture of titanium dioxide, calcium fluoride, and sulphuric acid. Titanium tetrafluoride absorbs ammonia with the development of heat, forming in the cold **titanium tetrammino-tetrafluoride,** $TiF_4.4NH_3$; and at 120°, **titanium diamminotetrafluoride,** $TiF_4.2NH_3$, which sublimes without decomposition, and dissolves in water, forming a clear soln.

which slowly deposits titanic acid when boiled. With pyridine, it forms a white crystalline solid, $TiF_4.C_5H_5N$. No action was observed with the phosphorus chlorides ; but at 30°, phosphoryl chloride reacts, furnishing titanium tetrachloride : $3TiF_4+4POCl_3=3TiCl_4+4POF_3$. No reaction was observed with arsenic tri-chloride ; or with carbon disulphide, or carbon tetrachloride. It dissolves in dried alcohol with the evolution of heat, and the soln. when evaporated over phosphorus pentoxide, in vacuo, furnishes a crystalline mass of **titanium alcoholotetrafluoride,** $TiF_4.C_2H_5OH$. No reaction was observed with silicon tetrachloride, or silicon tetrabromide ; but·O. Ruff and K. Albert found that when heated with trichloro-silane for a day at 100°, titanium tetrafluoride is converted into the tetrachloride and trifluorosilane, $SiHF_3$. O. Ruff and R. Ipsen found that at a red heat titanium tetrafluoride is reduced to titanium by sodium, calcium, magnesium, boron, alu-minium, and iron ; but copper and silicon reduce it only to titanium trifluoride. No action was observed with chromic trioxide.

According to A. Piccini, pertitanic acid, $TiO_3.nH_2O$, forms a number of complex salts with various acids, for example, when a soln. of titanium fluoride is oxidized with hydrogen dioxide, and treated with an alkali or alkaline earth fluoride, crystal-line **oxyfluopertitanates** are formed. These salts are derivatives of titanium trioxide with one oxygen atom replaced by two atoms of fluorine :

$$\overset{\text{F}}{\underset{\text{F}}{\cdots}}\!>\!Ti\!<\!\overset{O}{\underset{O}{\cdot}} \qquad\qquad \overset{\text{H.F}=\text{F}}{\underset{\text{H.F}=\text{F}}{}}\!>\!Ti\!<\!\overset{O}{\underset{O}{\cdot}}$$

Titanium peroxyfluoride.　　　　　　Hydroxyfluopertitanic acid.

As A. Mazzucchelli pointed out, the introduction of an active oxygen atom into the mol. of titanium dioxide, is favourable to the formation of complex anions. They are decomposed by hydrofluoric acid, forming hydrogen dioxide and titanium tetrafluoride (or hydrofluotitanic acid) : $TiO_2F_2+2HF=TiF_4+H_2O_2$. This is taken as evidence that the two oxygen atoms form a bivalent radicle eq. to two fluorine atoms. A. Piccini prepared **hydro-oxyfluopertitanic acid,** $H_2TiO_2F_4$, or $TiO_2F_2.2HF$, in soln. by adding barium oxyfluopertitanate, in slight excess, to well-cooled dil. sulphuric acid (4–5 per cent.) contained in a platinum dish, filtering (using a silver funnel) from the barium sulphate and excess of oxyfluopertitanate, and cautiously precipitating the traces of barium in soln. with dil. sulphuric acid. When the acid is neutralized with ammonia, it is probable that normal **ammonium oxyfluopertitanate,** $(NH_4)_2TiO_2F_4$, or $TiO_2F_2.2NH_4F$, is formed, but it was not obtained in definite crystals. Potassium carbonate under similar conditions furnishes the analogous potassium salt. If the acid be neutralized with ammonia and ammonium fluoride be added, octahedral **ammonium oxyfluopertitanate,** $3NH_4F.TiO_2F_2$, or $(NH_4)_2TiO_2F_4.NH_4F$, is formed. Similarly also when an excess of ammonia is added to hydro-oxyfluopertitanic acid. The same salt is formed when a soln. of ammonium fluotitanate, $3NH_4F.TiF_3$, is washed with a conc. soln. of ammonium fluoride, moistened with alcohol, and exposed to the air. The violet product gradually changes into an intense yellow mass, and when crystal-lized from its aq. soln., furnishes octahedral crystals. E. Petersen's idea that the oxidation does not occur is incorrect. The salt is also produced when ammonium oxyfluopertitanate is treated with hydrogen dioxide in the presence of an excess of ammonia and ammonium fluoride. The salt forms yellow octahedral crystals which are soluble in water. A. Mazzucchelli and C. Barbero compared the electrolytic potential of the soln. with that of hydrogen dioxide. The aq. soln. decolorizes potassium permanganate ; ammonium hydroxide precipitates a pale yellow flocculent mass which dissolves in sulphuric acid, forming an orange-red soln. The action of hydrofluoric acid is indicated above.

The octahedral crystals just mentioned are usually accompanied by yellow acicular crystals of ammonium oxyfluotitanate, $3NH_4F.2TiO_2F_2$, particularly if no excess of ammonium fluoride is present. The same salt is formed by oxidizing a 5 per cent. soln. of titanium dioxide in sulphuric acid, with barium dioxide ; adding ammonia to the filtrate

until the precipitate no longer redissolves; and pouring the liquid into a conc. soln. of ammonium fluoride containing an excess of ammonia. The soln. is then crystallized in vacuo. A. Piccini also made $Ti_5O_4F_{12}.9NH_4F$, or $3(TiF_4.2NH_4F).2TiO_2.3NH_4F$. He found that if an excess of ammonia is added to a soln. of ammonium fluotitanate, $TiF.2NH_4F$, the whole of the titanic acid is precipitated. If, however, ammonia is added drop by drop to the warm soln. of the fluoride, the white precipitate which first forms redissolves later, until at a certain point the liquid has merely an opalescent appearance; if now allowed to remain, a white, crystalline precipitate of the composition just indicated, settles out. It is completely soluble in a soln. of ammonium fluotitanate, but is decomposed by water, titanic acid being precipitated.

A. Piccini prepared normal **potassium oxyfluopertitanate,** $K_2TiO_2F_4$, or $TiO_2F_2.2KF$, as a yellow crystalline powder by neutralizing a soln. of the acid with potassium hydroxide or carbonate; by the action of hydrogen dioxide on potassium fluotitanate; or by treating a soln. of the ammonium salt, $3NH_4F.TiO_2F_2$, with potassium chloride. The salt is probably isomorphous with potassium fluotitanate, K_2TiF_6. A. Piccini prepared **barium oxyfluopertitanate,** $BaTiO_2F_4$, or $TiO_2F_2.BaF_2$, as a flocculent precipitate by adding barium nitrate to a soln. of the octahedral ammonium fluoxypertitanate. Sometimes also, under conditions which are not accurately known, this was accompanied by a crystalline barium compound, probably $2TiO_2F_2.3BaF_2$, corresponding with the octahedral ammonium salt. When the amorphous barium salt is gently heated, oxygen is evolved and the yellow colour becomes white; but at a higher temp. it parts with its fluorine, and is converted into a white mass of barium metatitanate, $BaO.TiO_2$. The white intermediate product obtained at $150°-160°$ has the composition $BaF_2.TiO_2F_2$, or titanium barium oxyfluoride. It is easily soluble in dil. acids, and cannot therefore be a mixture containing titanium dioxide.

§ 11. Hydrofluotitanic Acid, and the Fluotitanates

As J. J. Berzelius [1] supposed, it is probable that a soln. of titanium dioxide in hydrofluoric acid contains **hydrofluotitanic acid,** H_2TiF_6, because heat is evolved during the reaction, and when the liquid is neutralized with bases, stable **fluotitanates,** R'_2TiF_6, are formed. J. J. Berzelius said that a soln. of the acid is obtained by decomposing crystalline titanium tetrafluoride with water; and by dissolving titanium in a warm mixture of hydrofluoric and nitric acids. W. von Kowalewsky found that the electrical conductivity of conc. hydrofluoric acid was 0.621, and that when 5 grms. of titanium dioxide were dissolved in 49.7 grms. of the acid, the conductivity rose to 0.690. This is taken to mean that the soln. contains a complex acid, H_2TiF_6, which is a better conductor than hydrofluoric acid.

F. Fischer and K. Thiele made hydrofluotitanic acid by adding lead carbonate to the acid so prepared, and treating the precipitated lead fluotitanate with hydrogen sulphide. Air was then bubbled through the filtered liquid for about an hour so as to remove the hydrogen sulphide. J. Thomsen gave for the heat of formation of hydrofluotitanic acid, $\{Ti(OH)_4, 6HF, aq.\} = 30.9$ Cals. Hydrofluotitanic acid is known only in soln.; the free acid has not been isolated. The fluotitanates are usually sparingly soluble in water. According to J. J. Berzelius, J. C. G. de Marignac, and R. Weber, the fluotitanates are isomorphous with the corresponding fluosilicates, fluozirconates, and fluostannates. The complex nature of the fluotitanates was investigated by A. Mazzucchelli. O. Ruff and R. Ipsen showed that while sulphuric acid liberates volatile silicon tetrafluoride from the fluosilicates, titanium tetrafluoride is not vaporized when a fluotitanate is treated with sulphuric acid, but is converted quantitatively into titanium dioxide. F. Fischer and K. Thiele showed that an aq. soln. of the acid attacks glass, but does not react with neutral hydrogen dioxide, potassium ferrocyanide, or silver nitrate; potassium salts give a white precipitate, and conc. sulphuric acid decomposes the soln. with the evolution of hydrogen.

J. J. Berzelius obtained normal **ammonium fluotitanate,** $(NH_4)_2TiF_6$, by adding ammonia to a soln. of titanium tetrafluoride, so long as the precipitate first formed redissolved, and evaporating the soln. to the point of crystallization. A. Piccini also made this salt. The brilliant scaly crystals were shown by J. C. G. de Marignac to belong to the trigonal system, and to be isomorphous with the corresponding fluostannate. The crystals do not lose weight at 100°; but when the salt is distilled in a platinum vessel, at a temp. below redness, J. J. Berzelius said that it yielded a sublimate of ammonium fluoride, and there remained what he regarded as $NH_4F.TiF_4$, which fused at an incipient red heat, and sublimed unchanged in flakes which were soluble in water, and had a rough acid taste. After precipitating the titanium dioxide by adding an excess of potash-lye, the liquid smelled of ammonia. According to J. C. G. de Marignac, if an acidic or ammoniacal soln. of ammonium fluotitanate be mixed with an excess of ammonium fluoride, and allowed to crystallize, tetragonal crystals of **ammonium heptafluotitanate,** $3NH_4F.TiF_4$, are produced. The doubly-refracting crystals were said to be isomorphous with the corresponding fluosilicate. H. Baker obtained dendritic and rectangular crystals by the evaporation of a soln. of titanium dioxide in hydrofluoric acid, containing ammonium fluoride, and nearly neutralized with ammonia. E. Ebler and E. Schott prepared water-clear crystals of **hydrazine fluotitanate,** $(N_2H_5)_2TiF_6.2H_2O$, by dissolving titanium dioxide in cold fuming hydrofluoric acid in the proportions required to form hydrofluotitanic acid, adding 50 per cent. aq. hydrazine hydrate until the mixture was just alkaline, and evaporating the clear soln. in vacuo over sulphuric acid. E. Ebler and E. Schott prepared hydroxylamine fluotitanate, $(NH_3O)_2.H_2TiF_6$, by adding 2 per cent. hydroxylamine to a cooled soln. of hydrofluotitanic acid, and evaporating the soln. in vacuo; the salt separates from methyl alcohol in white crystals. With quadrivalent titanium, hydroxylamine gives the same yellow coloration, caused by the formation of a higher oxide of titanium, as is produced by hydrogen dioxide.

P. Engelskirchen made dihydrated **lithium fluotitanate,** $Li_2TiF_6.2H_2O$, by dissolving lithium carbonate in hydrofluotitanic acid. The crystals effloresce on exposure to air, and they are readily soluble in water. Alcohol added to the aq. soln. precipitates a microcrystalline powder; while the slow evaporation of the aq. soln. gives long, needle-like crystals. J. J. Berzelius obtained indistinct crystals of **sodium fluotitanate,** Na_2TiF_6, as a saline crust by evaporating the soln. obtained by adding sodium hydroxide to a soln. of the tetrafluoride until a permanent precipitate begins to form. M. A. Hunter employed a similar process. J. C. G. de Marignac obtained hexagonal prisms by the very slow evaporation of the soln., and they appeared to be isomorphous with the corresponding fluosilicate. J. J. Berzelius said that the sodium salt is more soluble in water than the potassium

compound. J. C. G. de Marignac found that the mother-liquor containing an excess of sodium fluoride and hydrofluoric acid, deposited crystals of **sodium hydrofluotitanate,** $Na_2TiF_6.NaHF_2$, in rhombic prisms with the axial ratios $a:b:c=0.5168:1:0.4663$. When heated on platinum foil, the salt decrepitates and gives off 7.65 per cent. of hydrogen fluoride, without melting. The salt is completely soluble in water, and the aq. soln. gives off carbon dioxide when treated with ammonium carbonate.

According to G. Marchetti, anhydrous **potassium fluotitanate,** K_2TiF_6, is prepared by adding the theoretical quantity of potassium hydrofluoride to a soln. of titanium dioxide in an excess of hydrofluoric acid. It crystallizes in small, very lustrous leaflets, which are denser than the crystals of the monohydrated fluotitanate, $K_2TiF_6.H_2O$. It can be crystallized without change from hot hydrofluoric acid, but when dissolved in water it is completely converted into the hydrated salt. Conversely, when the hydrated salt is dissolved in conc. hydrofluoric or hydrochloric acid, it is converted into the anhydrous salt. L. Weiss and H. Kaiser said that the anhydrous salt is most conveniently made by fusing rutile with potassium hydrofluoride and crystallizing the product from water containing a little hydrofluoric acid. Gebrüder Siemens made the alkali fluotitanates by adding hydrofluoric acid to a paste made of titanic acid and potassium fluoride. F. Stolba found that 100 parts of water at 21° dissolve 1.27 parts of the salt; it is less soluble in soln. of alkali salts like potassium sulphate or nitrate; and when treated with potassium hydroxide, it decomposes: $K_2TiF_6+4KOH=6KF+Ti(OH)_4$, a reaction which can be employed for the volumetric determination of the hydrofluotitanic acid. According to O. Ruff and R. Ipsen, the salt is not decomposed when heated in a stream of hydrogen fluoride. J. J. Berzelius obtained **hydrated potassium fluotitanate,** $K_2TiF_6.H_2O$, by a process analogous to that employed for sodium fluotitanate. It is also obtained, as just indicated, from the anhydrous salt. J. J. Berzelius said the scaly crystals resemble those of boric acid, and when dried they become milk-white, and exhibit a silky lustre. J. C. G. de Marignac likened the crystals to those of the corresponding stannic salt, and found them isomorphous with potassium oxyfluo-columbate, and -tungstate. He said the crystals belong to the monoclinic system with the axial ratios $a:b:c=0.9924:1:1.0520$, and $\beta=98°\ 42'$. H. Töpsöe gave 2.992 for the sp. gr. The crystals lose all their water at 100°. According to J. J. Berzelius, when the salt is heated, water and titanium fluoride are given off, and at a white heat the salt melts without undergoing any further change. It dissolves readily in water without decomposition. J. C. G. de Marignac said that the salt is sparingly soluble in cold water, but readily soluble in boiling water, and that 100 parts of water dissolve S parts of K_2TiF_6, at

	0°	3°	6°	10°	14°	20°
S . . .	0.556	0.667	0.775	0.909	1.042	1.28

L. Weiss and H. Kaiser said that at 20°, 100 parts of water dissolve 1.28 parts of the salt, and at 100°, 10.64 parts; much less is dissolved in the presence of hydrofluoric acid. G. Krüss and L. F. Nilson said that the salt is more soluble in a soln. of potassium oxyfluocolumbate. R. D. Hall and E. F. Smith said that the solubility in water is increased by hydrogen dioxide, and the soln. becomes deep yellow. Colourless crystals can be obtained from the soln. The addition of hydrofluoric acid bleaches the yellow soln. R. D. Hall found that the presence of potassium bromide or iodide lowers the solubility of the salts in water; and the crystals obtained from the soln. are associated with these halides. F. Wöhler found that while the titanic acid is immediately precipitated from the hot soln., this is not so with the cold soln. J. J. Berzelius said that when the salt is fused with potassium hydrosulphate, only a small proportion of titanium tetrafluoride is given off. The salt is decomposed with vivid incandescence when heated with potassium, and titanium and potassium fluoride are formed. L. Weiss and H. Kaiser observed a similar reaction with sodium; and when aluminium is added to the fused salt, aluminium

titanide, Ti_2Al_3, is formed. C. F. Rammelsberg reduced the soln. to titanium trifluoride by zinc and hydrochloric acid.

P. Engelskirchen prepared **rubidium fluotitanate,** Rb_2TiF_6, by adding rubidium acetate to a soln. of titanium tetrafluoride. M. E. Pennington made this salt by crystallization from a soln. of rubidium fluoride and titanium fluoride. The salt is purified by recrystallization from water. The small hexagonal plates are sparingly soluble in cold water, and more readily soluble in hot water ; the salt is precipitated by alcohol from the aq. soln. He also made **cæsium fluotitanate,** Cs_2TiF_6, in small columnar crystals by crystallization from a soln. of cæsium carbonate in hydro-fluotitanic acid. The salt dissolves more readily in hot than in cold water ; and the solubility is greater than in the case of the rubidium salt. H. Behrens and P. D. C. Kley discussed the formation of these salts in microchemical analysis. M. E. Pennington found that when cæsium fluoride is added to a conc. soln. of titanium tetrafluoride, small lustrous crystals of **cæsium octofluotitanate,** Cs_4TiF_8, are produced. There is no loss of weight at $100°$; the salt is not decomposed by water ; and it is more soluble than the fluotantalate, $Cs_{15}TaF_{20}$.

J. J. Berzelius prepared tetrahydrated **copper fluotitanate,** $CuTiF_6.4H_2O$, by crystallization from a mixed soln. of the component salts. The pale, bluish-green, acicular or tabular crystals were found by J. C. G. de Marignac to belong to the monoclinic system, and to have the axial ratios $a : b : c = 0.7471 : 1 : 0.5564$, and $\beta = 104° 9'$. The crystals are isomorphous with the corresponding fluosilicate and fluostannate. They lose no water at $100°$; and, according to J. J. Berzelius, they dissolve in water with partial decomposition ; and readily and completely in acidulated water. If the aq. soln. of this be mixed with ammonium fluoride, and allowed to evaporate spontaneously, or at a gentle heat, J. C. G. de Marignac obtained ditetragonal bipyramidal crystals of **ammonium copper fluotitanate,** $CuF_2.NH_4F.TiF_4.4H_2O$, with the axial ratio $a : c = 1 : 1.0729$. The crystals effloresce in air, and lose their water when warmed. They are soluble in cold water. Similar crystals of potassium copper fluotitanate, $CuF_2.KF.TiF_4.4H_2O$, were obtained by an analogous process. The yield is smaller than with the ammonium salt on account of the lower solubility of potassium fluotitanate. J. C. G. de Marignac obtained a crystalline, deliquescent **silver fluotitanate** by a process like that used for copper fluotitanate.

J. J. Berzelius evaporated a soln. of calcium carbonate in one of titanium tetrafluoride in hydrofluoric acid, and obtained prismatic crystals of **trihydrated calcium fluotitanate,** $CaTiF_6.3H_2O$. J. C. G. de Marignac prepared the same salt, and found the first crop of crystals to be isomorphous with strontium fluotitanate, and fluostannate, and they were assumed to be **dihydrated calcium fluotitanate,** $CaTiF_6.2H_2O$. According to J. J. Berzelius, the crystals dissolve in acidulated water without change, but they are decomposed by water alone. J. C. G. de Marignac made **dihydrated strontium fluotitanate,** $SrTiF_6.2H_2O$, in monoclinic crystals, with the axial ratios $a : b : c = 1.2066 : 1 : 1.2295$, and $\beta = 111° 6'$. At a temp. exceeding $100°$, the crystals lose water and hydrogen fluoride ; they dissolve in cold water ; and the soln. becomes turbid when boiled. P. Engelskirchen obtained a fine-grained crystalline precipitate of **barium fluotitanate,** $BaTiF_6$, by adding barium chloride to a soln. of hydrofluotitanic acid. The salt is sparingly soluble in water, but readily soluble in dil. hydrochloric or nitric acid. F. Emich obtained **hemihydrated barium fluotitanate,** $BaTiF_6.\frac{1}{2}H_2O$, as a coarse, crystalline precipi-tate by adding barium chloride to a hot aq. soln. of potassium fluotitanate. The salt loses water of crystallization only on prolonged heating at a dull red-heat ; when heated to a higher temp., it decomposes with formation of titanium tetra-fluoride.

J. J. Berzelius obtained **hexahydrated magnesium fluotitanate,** $MgTiF_6.6H_2O$, in long needle-like crystals by the spontaneous evaporation of a soln. of magnesium carbonate in hydrofluotitanic acid ; and J. C. G. de Marignac obtained hexagonal crystals isomorphous with the corresponding fluostannate. The crystals lost

18·2 per cent. of water at 100°, and 40·33 per cent. at 300°; some titanium tetra-fluoride is lost at the higher temp. J. C. G. de Marignac similarly made **hexahydrated zinc fluotitanate**, $ZnTiF_6.6H_2O$, in hexagonal crystals with the axial ratio $a : c = 1 : 0·513$; and isomorphous with the corresponding fluosilicate and stannate. B. Gossner found the sp. gr. to be 2·106. J. C. G. de Marignac's attempt to make a fluotitanate with more zinc fluoride was nugatory. P. Engelskirchen made **hexahydrated cadmium fluotitanate**, $CdTiF_6.6H_2O$, by evaporating a soln. of cadmium carbonate in hydrofluotitanic acid, or by treating the soln. with alcohol. The crystals appear in the form of needles, or hexagonal prisms. The salt effloresces slowly in air, and loses all its water over sulphuric acid. It is very soluble in water and in 50 per cent. alcohol. J. J. Berzelius obtained small colourless crystals of **lead fluotitanate.** They were sparingly soluble in water without decomposition. P. Engelskirchen obtained the *trihydrate*, $PbTiF_6.3H_2O$, by adding freshly precipitated lead carbonate to a filtered soln. of titanium dioxide in hot hydrofluoric acid; evaporating the soln. on a water-bath; and stirring the soln. while cooling. The crystals form in soln. containing a large excess of free hydrofluotitanic acid. They are pressed between filter-paper, washed with alcohol and ether, and dried for a day over calcium chloride. A boiling soln. of hydrofluotitanic acid and lead nitrate or acetate gives lead fluoride crystals on cooling to 50°. The colourless crystals dissolve in water with the separation of some lead fluoride. F. Fischer and K. Thiele found that on electrolysis of a soln. of lead fluotitanate a basic salt is precipitated on the lead anode. They obtained an acid salt in soln., but not in the solid state.

J. J. Berzelius, and J. C. G. de Marignac obtained hexagonal crystals of **hexahydrated manganese fluotitanate**, $MnTiF_6.6H_2O$, isomorphous with the corresponding fluosilicate. R. Weber prepared **ferrous fluotitanate**, $FeTiF_6.6H_2O$, in hexagonal yellowish green-crystals. J. J. Berzelius made **ferric fluotitanate** by the spontaneous evaporation of an aq. soln. of a mixture of the two salts. The pale yellow crystalline mass is decomposed by water. R. Weber obtained green crystals of **hexahydrated nickel fluotitanate**, $NiTiF_6.6H_2O$, from a soln. of nickel oxide and titanium dioxide in hydrofluoric acid. The salt is very soluble in water. P. Engelskirchen prepared **hexahydrated cobalt fluotitanate**, $CoTiF_6.6H_2O$, from a soln. of freshly precipitated cobalt carbonate in hydrofluotitanic acid, either by evaporation, or by the addition of alcohol. The red hexagonal prisms lose 3 mols of water at 100°–110°, and some hydrogen fluoride is then evolved. The salt is sparingly soluble in water, less so in 50 per cent. alcohol, and insoluble in absolute alcohol. A. Miolati and G. Rossi prepared **cobaltic hexamminofluotitanate**, or luteocobaltic fluotitanate, $2\{Co(NH_3)_6\}F_3.3TiF_4.2HF$, by adding a soln. of luteocobaltic carbonate or fluoride to a hydrofluoric acid soln. of titanic acid; the salt can be crystallized from water containing hydrogen fluoride, and it loses this gas at 110°. After long preservation in a desiccator over sulphuric acid, it assumes the composition $2Co(NH_3)_6.3TiF_4$.

§ 12. Titanium Chlorides

Three titanium chlorides have been prepared—the di-, tri-, and tetra-chlorides. The analysis of a titanium chloride by E. S. George[1] indicated half as much chlorine as is present in the tetrachloride (*q.v.*), but this product seems to have been very impure. According to F. Wöhler, **titanium dichloride,** $TiCl_2$, is probably formed in colourless soln. when titanium is dissolved in hydrochloric acid. Much hydrogen is, at the same time, evolved. O. F. von der Pfordten attributed the result obtained by F. Wöhler to the use of titanium containing sodium which reduced the salt to the dichloride. With metal free from sodium, O. F. von der Pfordten, E. Glatzel, and H. Moissan obtained a violet soln. of the trichloride. A. Stähler and H. Wirthwein favoured F. Wöhler's view. E. Knecht showed that the reduction of aq. soln. of titanium tetrachloride always furnishes the trichloride not the dichloride. In preparing the trichloride by reducing the tetrachloride with hydrogen (*q.v.*), J. J. Ebelmen obtained golden-yellow scales which he considered to be those of the dichloride, but C. Friedel and J. Guérin showed that it must have been an oxychloride. A. Piccini and L. Marino's attempt to make compounds of the type TiX_2 was not successful. C. Friedel and J. Guérin made the dichloride by heating the trichloride to redness in a stream of hydrogen. In order to ensure success, there must be an entire absence of air and moisture. They said that the trichloride *se dédouble*, forming the tetrachloride which distilled, and the dichloride which remained behind as a black powder. O. Ruff and F. Neumann used a similar mode of preparation, by reducing the tetrachloride to trichloride (*q.v.*), and transforming the latter in one operation. It is difficult to prepare a product free from titanium, and the trichloride and oxychloride by this process. A. Stähler and F. Bachran represented the reaction at 660°–700°, in an atm. of hydrogen, by $2TiCl_3 \rightleftharpoons TiCl_2 + TiCl_4$. O. F. von der Pfordten reduced titanium tetrachloride at ordinary temp. by sodium amalgam, and distilled off the unchanged tetrachloride in a current of carbon dioxide. He also said that titanium tetrachloride is reduced at ordinary temp. by hydrogen sulphide; $TiCl_4 + H_2S = TiCl_2 + 2HCl + S$; but A. Stähler and F. Bachran could not confirm this observation, though they did obtain $TiSCl_2$ and TiS_2. Titanium tetrachloride was found by O. Ruff and F. Neumann to be reduced to the dichloride by sodium amalgam, and at the same time some trichloride is formed by the interaction of the tetra- and di-chlorides. According to R. Schmidt, titanium dichloride, almost free from oxygen, is obtained by the thermal decomposition of titanium trichloride in a carbon tube at temp. not greatly exceeding 600°; if glass or quartz tubes are used, oxygen is abstracted from the silica with consequent production of oxygenated compounds. At 600° (0·02 mm.), titanium dichloride slowly volatilizes and is decomposed into the tri- and tetra-chlorides, which are deposited in the cooler portions of the tube. The effect is due to decomposition of the dichloride into titanium and titanium tetrachloride and reduction of the latter by unchanged dichloride to give the trichloride.

According to C. Friedel and J. Guérin, titanium dichloride is a blackish powder, which is occasionally in the form of flakes, very unstable in air, and in the presence of moisture (with the latter it becomes lighter in colour). Thrown into water it hisses like red-hot iron and dissolves, with a copious evolution of hydrogen. On the addition of ammonia to this soln., a black precipitate is formed, hydrogen being evolved at the same time. The black precipitate gradually changes to blue,

and eventually to white, and on throwing a few drops of water upon the dichloride (taking care not to moisten it completely), sufficient heat is generated to cause it to take fire in the air. On being heated in air, the di-chloride burns like tinder, fumes of the tetrachloride being evolved, and titanic acid remaining behind. It is insoluble in ether, carbon disulphide, and titanium tetrachloride, and on being heated gently with absolute alcohol, hydrogen is evolved, and a yellowish liquid formed, which on the addition of ammonia furnishes a blue-black precipitate. Dry ammonia gas passed over the dichloride at a red heat gives rise to the formation of the nitride, Ti_3N_4, hydrogen being set free according to the equation, $3TiCl_2 + 4NH_3 = Ti_3N_4 + 6HCl + 3H_2$. Bromine forms with the dichloride a fuming liquid, which boils at about 180°, and is probably $TiCl_2Br_2$. The various descriptions of the properties of titanium dichloride are not in agreement. Titanium dichloride is a black powder which dissolves in water and in alcohol with a brown coloration, but it is insoluble in ether. On exposure to the air, the aq. soln. deposits titanic acid; the alcoholic soln. remains clear, but contains organic chlorine products. With potassium thiocyanate and ether, titanium dichloride exhibits a delicate and characteristic reaction; the ether acquires a dark brown colour. O. Ruff and F. Neumann found that the dichloride does not vaporize appreciably at 600°. It is very reactive. H. Goerges and A. Stähler said that the black powder dissolved in fuming hydrochloric acid, forming a green soln. which contained bivalent titanium, and gave the following reactions. On boiling in the air, it became violet, with the formation of tervalent titanium. Nitric acid oxidized it first to the tervalent condition (violet), and then to the quadrivalent (colourless). Ammonium hydroxide, carbonate, or sulphide gave first a dark brown precipitate, which decomposed after a short time with the rapid evolution of hydrogen. Potassium thiocyanate gave a green soln., and sodium acetate, a green precipitate of the titanous acetate. On heating with mercuric chloride, calomel was precipitated. Indications were obtained that when the trichloride is reduced by hydrogen at a bright red heat, some metallic titanium is formed. When the soln. of the dichloride in hydrochloric acid is evaporated in vacuo, the crystals which are formed were supposed to be those of a hydrate, $TiCl_2.nH_2O$. When a hydrochloric acid soln. of titanium dichloride is mixed with one of titanium tetrachloride a violet coloration is produced owing to the formation of the trichloride. M. Coblens and J. K. Bernstein found that titanous chloride reduces nitric oxide and nitrous oxide to ammonia. Nitric oxide is evolved, and no ammonia is formed when a sodium nitrite soln. is added drop by drop to an acid titanous chloride soln. Titanous chloride has a specific decomposing effect on nitrous and hyponitrous acids. The gases escape before any appreciable reduction can take place.

Anhydrous **titanium trichloride,** $TiCl_3$, or *titanous chloride*, or as it was originally called *titanium sesquichloride*, was made by J. J. Ebelmen [2] by passing dried hydrogen through warm liquid titanium tetrachloride, and leading the mixture of hydrogen and tetrachloride vapour through a red-hot tube; the trichloride collects as a mass of dark violet scales in the tube just beyond the heated zone. The current of hydrogen is continued till the tube is cold, and the salt is preserved out of contact with air. H. Goerges and A. Stähler made the trichloride by this reaction using a porcelain tube heated electrically by a wire spiral inside the tube, and surrounded by a glass tube cooled externally by a rapid current of cold water. The mixed gases traverse the space between the tubes. The reaction begins about 600°, and at 785°, the percentage decomposition was 21·7, and at 1200°, 94·3. The trichloride collects on the surface of the cold tube as a fine reddish-violet powder. According to F. Meyer and co-workers, titanium trichloride may be prepared by the reduction of the tetrachloride by means of hydrogen, provided that the products of the reaction are quickly cooled, and the hydrogen chloride is removed by means of metallic titanium. The trichloride so prepared consists of large violet crystals, which are fairly stable in the air. The reduction is not direct, but three reactions, $TiCl_4 + H_2 = TiCl_2 + 2HCl$; $TiCl_2 + TiCl_4 = 2TiCl_3$; $2TiCl_3 + 2HCl = 2TiCl_4 + H_2$,

may proceed simultaneously. F. Emich passed electric sparks through a mixture of hydrogen, and tetrachloride vapour, and obtained a deposit of violet crystals; while F. Böck and L. Moser subjected a mixture of dry hydrogen and titanium tetrachloride vapour to the action of the silent electric discharge. At ordinary temp. a dark brown deposit was formed containing a mixture of the tri- and tetra-chlorides. When heated in vacuo at 100° the tetrachloride was removed, leaving the brown trichloride in which the tetrachloride had been occluded. Between 200° and 400°, the violet trichloride was formed free from occluded tetrachloride. The brown substance was considered to be a labile, allotropic, or monotropic form of the trichloride which changes to the violet form between 150° and 200° in vacuo. The change from brown to violet trichloride is not reversible; for when the temp. was gradually raised above that at which transformation takes place, the heating curve of the brown modification did not differ appreciably from that of the cooling curve of the violet modification thereby formed. C. Friedel and J. Guérin made the trichloride by heating a mixture of the tetrachloride and reduced silver in a sealed tube at 180°–200°: $TiCl_4 + Ag \rightleftharpoons AgCl + TiCl_3$; and T. E. Thorpe, by shaking the tetrachloride with mercury in a sealed tube: $TiCl_4 + Hg \rightleftharpoons HgCl + TiCl_3$. The reaction is rapid and complete at 98°, but between 200° and 250° the reverse change is marked. K. Seubert and A. Schmidt reduced titanium tetrachloride vapour to the trichloride by passing it over magnesium at a red heat. L. Lévy obtained the trichloride by heating to 100° a mixture of titanium tetrachloride and mercury diethyl in an atm. of carbon dioxide: $2TiCl_4 + Hg(C_2H_5)_2 = HgCl_2 + C_4H_{10} + 2TiCl_3$. Titanium tetrachloride in benzene soln. is also partially reduced by mercury diphenyl. O. Ruff and F. Neumann found that at slightly elevated temp. titanium tetrachloride is reduced to the trichloride by aluminium, magnesium, zinc, mercury, silver, arsenic, and tin. Aluminium trichloride acts as a catalyst, and in its presence the reduction by aluminium is quantitative at 200°. The conditions for the reduc-tion of the tetra- to the tri-chloride were studied by F. Meyer and co-workers. They found that the two requirements for the successful preparation of coarsely crystalline titanium trichloride by reduction of the tetrachloride are, first, a steep temperature gradient to ensure rapid cooling, and secondly, the depression of the hydrogen chloride concentration. The first condition is best secured by using a non-conducting (quartz) tube of narrow bore, with air cooling at the receiver end. The second is attained most easily by the addition of metallic titanium to the re-action mixture. This subject was discussed by R. Schmidt.

Anhydrous titanium trichloride forms dark violet, scaly crystals which, according to C. Friedel and J. Guérin, are isomorphous with those of ferric chloride. Titanium trichloride deliquesces on exposure to air, and decomposes rapidly. It oxidizes slowly in dry air, rapidly in moist air. The trichloride is non-volatile, but H. Goerges and A. Stähler found that when heated to 440°, it decomposes into the di- and tetra-chlorides: $2TiCl_3 \rightleftharpoons TiCl_2 + TiCl_4$; whereas to make it from the tetrachloride and hydrogen, a temp. of 600° is necessary; even at ordinary temp. the trichloride decomposes and the vap. press. of the tetrachloride produced is appreciable. J. J. Ebelmen said that the trichloride decomposes at ordinary temp., and C. Friedel and J. Guérin observed that in closed vessels, the trichloride is decomposed, for the surface becomes white, and unlike the freshly prepared trichloride, it fumes in moist air. H. Goerges and A. Stähler found that the trichloride is best preserved in an atm. of dry carbon dioxide. O. Ruff and F. Neumann found that titanium tri-chloride is not decomposed at 425° under one mm. press., but at 450° the tetra-chloride and dichloride are formed. When the trichloride is heated in contact with air, J. J. Ebelmen observed that the tetrachloride is given off; and some titanium dioxide remains. When dissolved in water it forms a violet-red soln. F. Böck and L. Moser gave for the heat of soln. (brown, $TiCl_3$, Aq.)=48·150–48·837 Cals.; and (violet, $TiCl_3$, Aq.)=44·287–45·800 Cals. in agreement with the view that the brown and violet forms are monotropic modifications. G. S. Forbes and L. P. Hall calculated −0·349 to −0·399 volt for the normal potential of the

reduction Ti···+H⇌Ti··+H· from the measurements of the e.m.f. of the cell ⁻Hg|TiCl₃,TiCl₂, 0·05N-HCl|4N-KCl|0·1N-HCl|Hg·. H. Goerges and A. Stähler observed that a mixture of the trichloride and liquid ammonia in a sealed tube furnishes a yellow emulsion ; a part of the trichloride seems to pass into soln.

According to R. Weber, a soln. of titanium trichloride is obtained by dissolving titanium in hydrochloric acid, and, according to C. F. Rammelsberg, no lower chloride is produced—*vide* the dichloride. E. Knecht reduced a soln. of the tetrachloride with tin and hydrochloric acid, and removed the tin with hydrogen sulphide ; he also obtained it by reducing a soln. of titanium dioxide in hydrochloric acid by zinc and hydrochloric acid ; and C. F. Rammelsberg similarly reduced a cold or boiling soln. of potassium chlorotitanate. J. N. von Fuchs, F. Pisani, and O. F. von der Pfordten also used zinc and hydrochloric acid for the reduction. E. Glatzel obtained a green mass of *tetrahydrated titanium trichloride*, TiCl₃.4H₂O, by evaporating a soln. of titanium in hydrochloric acid. The product dissolves in water, but the liquid is not clear ; it easily oxidizes on exposure to air. E. Polidori had doubts about this hydrate ; and H. Goerges and A. Stähler could obtain only the hydrated dichloride by E. Glatzel's method. E. Polidori made violet **hexahydrated titanium trichloride**, TiCl₃.6H₂O, by reducing a soln. of the tetrachloride in 30 per cent. hydrochloric acid, by electrolysis with a carbon rod as positive electrode. The violet soln. was filtered through glass-wool, cooled with ice and salt ; and treated with a current of dry hydrogen chloride until the salt crystallized out. H. Spence also obtained the trichloride by the electrolytic reduction of a 20–25 per cent. soln. of the tetrachloride with dil. hydrochloric acid in the anode compartment ; using a lead cathode and a carbon or platinum-iridium anode, and 200 amp. per sq. metre, and 3 to 4 volts. The soln. was conc. under reduced press. until its sp. gr. at 65°–70°=1·5, when crystals of the hexahydrate were formed. Like chromium and vanadium trichlorides, titanium trichloride can exist in two forms—an unstable green hydrate, and a stable violet hydrate—for A. Stähler showed that if a conc. aq. soln. of the violet hydrate is covered with a layer of absolute ether and then sat. with hydrogen chloride and kept cool meanwhile, the green, unstable hydrate separates out in crystals ; when the hydrogen chloride is washed out with ether, the violet compound is again formed. Green vanadium trichloride does not change in colour when treated with ethereal hydrogen chloride. According to E. Polidori, the hexahydrated trichloride is deliquescent, and oxidizes very slowly in dry air, but rapidly in moist air.

According to J. J. Ebelmen, the violet-red soln. of titanium trichloride in water is decolorized on exposure to air owing to the formation of titanic acid ; the presence of a little hydrochloric acid prevents the precipitation of the titanic acid. When the aq. soln. is evaporated to dryness, it furnishes a blue oxy-chloride. When the aq. soln. is treated with potassium hydroxide, sodium hydroxide, or aq. ammonia, dark brown titanium trihydroxide is precipitated, and this quickly changes to black, blue, and finally white titanic acid, and hydrogen is at the same time evolved. Alkali carbonates behave similarly, but carbon dioxide and then hydrogen are evolved. The soln. is not appreciably changed by hydrogen sulphide ; ammonium sulphide acts like aq. ammonia. Nitric acid decolorizes the soln. with the evolution of nitric oxide ; and, according to E. Knecht, some ammonia is formed. The reduction of nitric acid by titanous salts has been studied by L. H. Milligan and G. R. Gillette. As indicated below, O. C. M. Davis prepared **titanium nitrogen hexachlorotetrasulphide,** N₄S₄.2TiCl₃, by the action of titanium tetrachloride on nitrogen sulphide—*vide* the addition compounds of titanium tetrachloride. A. Stähler prepared **rubidium titanous pentachloride,** or **rubidium chlorotitanite,** TiCl₃.2RbCl.H₂O, by passing hydrogen chloride into an aq. soln. of a mixture of rubidium and titanium chlorides, heated on a water-bath. The salt is green, and it forms a violet soln. with water. Green **cæsium titanous pentachloride,** or **cæsium chlorotitanite,** TiCl₃.2CsCl.H₂O, was obtained in a similar way.

A soln. of titanium trichloride, said J. J. Ebelmen, *est un réductif des plus*

énergiques ; and E. Knecht and E. Hibbert found it is a more powerful reducing agent than stannous chloride. According to J. J. Ebelmen, potassium permanganate decolorizes the soln. and is itself decolorized. When sulphur dioxide is heated with the trichloride, sulphur is deposited, and E. Knecht found that hydrosulphurous acid is formed as an intermediate product. J. J. Ebelmen showed that mercury, silver, and gold are precipitated by the trichloride from soln. of their salts. According to A. Stähler and F. Bachran, titanium trichloride reacts with a soln. of gold chloride producing colloidal gold analogous to purple of Cassius, and the reaction will detect one part of gold in 20 million parts of water. Chlorates and perchlorates are reduced to chlorides ; hydrogen dioxide to water ; and persulphates to sulphates. According to A. Monnier, platinum, iridium, and palladium chlorides give the respective metals. Selenates give red selenium ; and tellurates give tellurium when heated. Tungstates are reduced, giving a blue colour ; molybdates, a brown colour ; and vanadates are decolorized. Chromates and dichromates give green chromic salts. J. J. Ebelmen said that a trace of titanium trichloride brings violet chromic chloride into soln. Many organic substances are reduced by titanium trichloride. An excess of the trichloride was found by E. Knecht to reduce cupric sulphate to the metal. L. Moser described the application of the reaction for the determination of copper. J. J. Ebelmen showed that the trichloride reduces ferric to ferrous salts, and E. Knecht and E. Hibbert utilized the reaction for the volumetric determination of iron : $TiCl_3 + FeCl_3 = TiCl_4 + FeCl_2$. The end of the reaction is shown by alkali thiocyanate or methylene-blue as an external indicator. E. Knecht and co-workers, E. Zintl and A. Rauch, W. S. Hendrixson, etc., showed that the soln. of titanium trichloride (or sulphate) can also be used for the determination of copper, tin, chromium, hydrogen dioxide, chlorates, bromates, iodates, perchlorates, nitrates, hydroxylamine, hyposulphites, ferricyanides, and numerous organic compounds, and dye-stuffs. E. Zintl and A. Rauch, and W. S. Hendrixson discussed the application to ferricyanides, iodates, etc. ; and I. M. Kolthoff and co-workers, and E. Zintl and A. Rauch, the titrometry of the trichloride.

E. S. George [3] discovered **titanium tetrachloride,** $TiCl_4$, in 1825 ; he obtained it by passing dried chlorine over titanium heated in a glass tube ; there is no reaction in the cold. The titanium available to E. S. George was shown by F. Wöhler to have been a carbonitride, and that in the reaction some cyanogen chloride is simultaneously produced and forms sulphur-yellow crystals. F. Wöhler also showed that while chlorine has but little action on titanium in the cold, the elements unite directly when warmed, forming the tetrachloride. E. Vigouroux and G. Arrivaut used ferrotitanium as a source of titanium ; if desired, most of the iron can be first removed by hydrochloric acid, and the residue heated in a stream of chlorine in a porcelain tube. The liquid was purified by fractional distillation. M. Billy purified titanium tetrachloride by treatment with sodium amalgam followed by fractional distillation between 135°–137° ; ethane tetrachloride was removed by distillation in a current of dry air at 120°. The tetrachloride was finally kept at its b.p. for 2 hrs. in the presence of metallic titanium. H. R. Ellis ignited a mixture of rutile and powdered aluminium ; heated the product in a current of chlorine ; and purified the product from silicon tetrachloride by fractional distillation. M. A. Hunter, and H. Goerges and A. Stähler heated titanium carbide in a stream of chlorine, and purified the product by fractional distillation. C. Friedel and J. Guérin also found that at a high temp. chlorine reacts with titanium dioxide : $TiO_2 + 2Cl_2 \rightleftharpoons TiCl_4 + O_2$. J. B. A. Dumas made the tetrachloride by passing chlorine over a red-hot mixture of titanium dioxide and carbon—even the heat of a spirit lamp, said F. Wöhler, is sufficient for the purpose. If rutile is used instead of titanium dioxide, some ferrous or ferric chloride is formed. The liquid which is condensed has a reddish colour owing to the presence of ferric chloride ; most of this can be removed by fractional distillation. J. I. Pierre, A. Demoly, O. F. von der Pfordten, V. Merz, and R. F. Wagner

used the chlorine-carbon process. O. Priesz found the temp. of the reaction can be reduced to 300° by adding a small proportion of chloride or oxide of cerium, zirconium, manganese, or a rare earth. F. de Carli used ferrotitanium in place of titanium. C. W. Watts and C. A. Bell passed carbon tetrachloride, chloroform, or a mixture of chlorine and carbon monoxide over red-hot titanium dioxide and obtained the tetrachloride: $TiO_2+2Cl_2+2CO=2CO_2+TiCl_4$. C. Renz used chloroform. O. Priesz found the yield is improved if a little carbon be mixed with the titanic oxide. The main reaction is represented: $TiO_2+2CHCl_3=TiCl_4+2CO+2HCl$. The temp. determines the nature of the products of the secondary reaction, carbon dioxide, carbonyl chloride, hexachlorobenzene, etc. L. Meyer observed no change in the action of carbon tetrachloride on titanium dioxide at a high temp.; but E. A. Demarçay found the action is fast at 440°, and he considered this to be one of the most convenient methods of preparation. H. E. Quantin studied the action of carbon tetrachloride on a number of metal oxides. F. Bourion made titanium tetrachloride by the action of the vapour of sulphur chloride, S_2Cl_2, and chlorine on red-hot titanium dioxide. The reaction is complicated by the formation of $2TiCl_4.SCl_4$.

J. B. A. Dumas freed the titanium tetrachloride from an excess of chlorine, which gives it a yellow colour, by agitation with small quantities of mercury, and distillation, two or three times, from mercury. F. Wöhler used copper; and A. Bertrand employed reduced iron. H. Rose, and A. Demoly rectified the tetrachloride by distillation, four or five times, over mercury or potassium; V. Merz distilled the liquid from sodium amalgam; R. F. Wagner distilled the crude liquid over sodium to remove hydrogen chloride, chlorine, and ferric chloride; and rectified the product by fractional distillation. O. F. von der Pfordten found that vanadium oxychloride imparts a yellow colour to the crude liquid, and is removed by the distillation over sodium. G. P. Baxter and G. J. Fertig described an elaborate method of purification for their at. wt. determination.

The physical properties of titanium tetrachloride.—Titanium tetrachloride at ordinary temp. is a transparent, colourless, mobile liquid. J. I. Pierre gave 1·76098 for the **specific gravity** at 0°/4°; J. H. Gladstone gave 1·744 at 10·5°; A. Stiefelhagen, 1·761 at 18°; and T. E. Thorpe, 1·76041 at 0°/4°; and 1·5222 at its b.p. O. Masson, and J. A. Groshans compared the mol. vol. and b.p. of the family of tetrachlorides. J. B. A. Dumas gave 6·836 (air, unity) or 197·4 (oxygen, 16) for the **vapour density** when the theoretical value is 190 (oxygen, 16). J. I. Pierre represented the **thermal expansion,** or the vols., v, occupied by unit vol. of liquid at $\theta°$, between 0° and 140°, when the vol. at 0° is unity, by the formula $v=1+0.0_39425690040\theta+0.0_51345793937\theta^2+0.0_9888044\theta^3$; and T. E. Thorpe, $v=1+0.0_398261.20\theta+0.0_6505528\theta^2+0.0_8513052\theta^3$. J. J. Saslawsky studied the relation of the expansion coeff. with the structure. J. B. A. Dumas gave for the **boiling point,** 135° at 763 mm.; J. I. Pierre, 136° at 762·3; T. E. Thorpe, 136·4° at 760; M. A. Hunter, 136·5°; H. R. Ellis, E. Vigouroux and G. Arrivaut, and A. Stähler, 136°; F. Emich, 134·8° at 735 mm.; P. A. Bond and H. T. Beach, 136° at 750 mm.; and B. F. Duppa, G. Gustavson, and C. Renz, 135°. J. I. Pierre said that the liquid remains clear at −25°; the **melting point** given by F. Emich, and W. Biltz and E. Meinecke, is −23°; W. H. Latimer, −30°; and by E. Haase, −25°. The **critical temperature** estimated by C. M. Guldberg is 358°. H. V. Regnault gave 0·18812 for the **specific heat** of the liquid between 13° and 99°; and 0·12897 for the sp. ht. of the vapour at constant press. between 163° and 271°. W. H. Latimer gave for the mol. ht., C_p:

°K	86·7°	92·8°	99·3°	194·6°	231·8°	247·7°	251·6°	294·3°
C_p	4·26	4·40	4·54	6·19	6·31	6·21	7·26*	7·32*

where the numbers marked with an asterisk refer to the liquid, the others to the solid. The **heat of fusion** at 25° is 11·77 cals. per gram; and the **entropy** at 25°, 59·51. F. Böch and L. Moser gave for the **heat of solution,** $(TiCl_4,Aq.)=59·03$

Cals. ; and J. Thomsen, 57·866 Cals. The last-named gave for the **heat of neutralization,** (TiCl₄aq., 4NaOHaq.)=47·664 Cals. ; and for the **heat of formation,** (TiO₂aq., 4HClaq.)=7·296 Cals. J. H. Gladstone gave for the **index of refraction** 1·5851 for the *A*-line ; 1·6039 for the *D*-line ; 1·6296 for the *F*-line ; and 1·6814 for the *H*-line ; for the **molecular refraction,** 65·20 ; and for the **molecular dispersion,** 10·74. H. Becquerel, and A. Stiefelhagen made some observations on this subject. A. Stiefelhagen gave for light of wave-length λ=358, 508, and 708μμ, μ=1·73447, 1·62574, and 1·58859, and μ²=1·77849+0·67263λ²(λ²−239·69²)⁻¹. H. H. Marvin studied the optical dispersion. H. Becquerel gave values for the index of refraction, for the **magnetic rotation,** and **magnetization.** He also made observations on the **spectrum.**

J. H. Mathews found the **dielectric constant** at 24° to be 2·73. W. von Kowalewsky measured the **electrical conductivity** of some aq. soln.—*vide infra.* A. Stälher and F. Bachran could not obtain less chlorinated products by the electrolysis of soln. of titanium tetrachloride in anhydrous hydrogen cyanide. B. Diethelm and F. Förster studied the electro-reduction of titanium sulphate soln. and found the current efficiency to be greater with a copper or lead electrode than with one of bright platinum, and the velocity of the reduction is smaller with a bright platinum electrode than with a platinized platinum electrode. They found for the reduction Ti····+H⇌Ti···+H·, the normal potential −0·056 volt at 18° ; and G. S. Forbes and L. P. Hall calculated for the reduction Ti····+2H⇌Ti··+2H· −0·33 volt at 18°.
The chemical properties of titanium tetrachloride.—K. Fajans studied the electronic structure of the titanium halides. The tetrachloride emits dense white fumes in air, but, added J. I. Pierre, although this occurs at ordinary temp., the fuming does not appear below 0°. Titanium tetrachloride is reduced by **hydrogen** above 600°, forming the tri- and di-chlorides (*q.v.*) ; and at a red heat H. Goerges and A. Stähler found some titanium is produced. They also passed a mixture of the tetrachloride and hydrogen through a porcelain tube at different temp., and found that as the temp. rises from 785° to 1200° the percentage decomposition rises from 21·7 to 94·3—*vide supra.* A state of equilibrium was probably reached in the hot zone; but the trichloride remained as a deposit in the porcelain tube. Increasing the proportion of the hydrogen raised the percentage decomposition ; and at a constant temp., it was found empirically that the ratio [TiCl₃]⁴/[TiCl₄]³ is approximately constant. When hydrogen chloride was added the percentage decomposition diminished. R. Schmidt found that at 600°, H₂+TiCl₄=2HCl+TiCl₂ ; and TiCl₂+TiCl₄=2TiCl₃. The trichloride is deposited in the cold part of the tube. E. A. Schneider's attempts to make *titano-chloroform,* TiHCl₃, or *titanium hydro-trichloride,* were unsuccessful. Dry hydrogen chloride reacts with titanium at 300°, forming a non-volatile substance. T. König and O. F. von der Pfordten found that with **water** it forms a series of oxychlorides, TiCl₃.OH ; TiCl₂(OH)₂ ; TiCl₂(OH)₃ ; and with an excess of water, Ti(OH)₄ is formed—*vide infra.* R. F. Wagner found that when titanium tetrachloride is dropped into water a turbid liquid is produced, but a clear soln. of orthotitanic acid in titanium tetrachloride can be obtained by adding water drop by drop to the tetrachloride with constant agitation. The liquid fumes in air, and the possible use of the fumes for producing clouds in aeroplane warfare was discussed by G. A. Richter, and H. W. Walker. O. F. von der Pfordten's comparison of the properties of the three chlorides is given in Table VI. W. von Kowalewsky showed that titanium tetrachloride dissolves in water with the evolution of much heat, and the hydrochloric acid liberated during the hydrolysis suffices to re-dissolve the precipitated hydroxide first formed without any corresponding change in the electrical conductivity. The value of the electrical conductivity shows that equilibrium is established before the hydrolysis is complete ; the hydrolysis is completed by boiling, or by heating in a sealed tube at 150°. The behaviour of titanium tetrachloride towards water is intermediate between silicon tetrachloride and tin tetrachloride. The same

remark applies to the tendency to form complex salts. A. Demoly evaporated a strongly acid soln. of the tetrachloride and obtained very hygroscopic crystals of **pentahydrated titanium tetrachloride**, $TiCl_4.5H_2O$, and in vacuo, over sulphuric acid, **dihydrated titanium tetrachloride**, $TiCl_4.2H_2O$, was formed. O. Ruff

and F. Eisner found that titanium tetrachloride reacts vigorously with **hydrogen fluoride ;** O. Ruff and R. Ipsen obtained a citron-yellow *titanium fluochloride,* approximately $TiClF_3$, by the action of titanium tetrachloride on hydrogen fluoride or silver fluoride. W. Biltz and E. Meinecke gave for the f.p. of mixtures of **chlorine** and titanium tetrachloride the results shown by Fig. 9. The · titanium tetrachloride freezes at $-22.5°$. The eutectic is at $-108°$ and 87.5 at. per cent. chlorine. P. Hautefeuille found that boiling titanium tetrachloride reacts with hydrogen iodide, forming the tetraiodide. J. J. Ebelmen said that in the cold, **hydrogen sulphide** reduces titanium tetrachloride to the dichloride, and at a higher temp., titanium disulphide is formed. The reaction was studied by O. F. von der Pfordten, who showed that the disulphide is formed at a red heat, but at intermediate temp. *titanium sulphochloride,* TiSCl, is formed. A. Stähler and F. Bachran could not verify this observation, but observed that the thiochloride, $TiSCl_2$, is formed. At $800°-850°$,

FIG. 9—Freezing-point Curves of $Cl_2 - TiCl_4$ Mixtures.

TiS_2 is produced. W. Biltz and E. Keunecke found that dry liquid hydrogen sulphide does not react with or dissolve titanium tetrachloride, but at a higher temp. there is formed a *monosulphohydrate,* $TiCl_4.H_2S$, and a *disulphohydrate,* $TiCl_4.2H_2S$, with the respective heats of formation 8.86 Cals. and 8.18 Cals. For the action of **sulphur chloride, chlorosulphonic acid, thionyl chloride, ammonia, nitrogen sulphide, hyponitrous acid, phosphine, phosphorus chlorides,** and **phosphoryl chloride,** *vide infra.* R. Wise found that selenium oxychloride dissolves 0.75 per cent. of titanium tetrachloride, and it forms the complex **titanium selenium dioxyoctochloride,** $TiCl_4.2SeOCl_2$. O. Ruff and H. Graf found that the reaction with **antimony pentafluoride** is quite violent, and titanium tetrafluoride is formed.

H. Rose showed that boiling titanium tetrachloride is not decomposed by **potassium ;** but the vapour passed over heated potassium or **sodium** is decomposed ; F. C. Robinson and C. C. Hutchins said that the reaction with sodium begins at $150°$. O. F. von der Pfordten, on the contrary, said that sodium and sodium amalgam reduce titanium tetrachloride to the dichloride at ordinary temp. A. C. Vournasos found at the temp. of boiling toluene, titanium tetrachloride is reduced by potassium partly to the dichloride and partly to titanium. A. Stähler and F. Bachran showed that the tetrachloride is reduced to the trichloride by heating it with finely powdered **aluminium, antimony, arsenic,** or **tin** in a sealed tube at $400°$. K. Seubert and A. Schmidt found that below redness **magnesium** reduces the tetrachloride to the trichloride and lower oxides, but the presence of titanium metal was not established with certainty. H. Goerges and A. Stähler obtained only a very slight reduction of the tetrachloride by **mercury** at ordinary temp. C. Friedel and

J. Guérin showed that when the vap. of titanium tetrachloride is passed over red-hot **ferric oxide,** rutile is formed, and ferric chloride volatilized.

P. Kohl found that the presence of many organic substances favours the electro-reduction of titanium tetrachloride. W. Dilthey made substitution products of titanium chloride; thus, with acetylmethylacetone he obtained *triacetylmethyl-acetonyltitanium titanichloride,* [Ti{O.C(CH$_3$) : C(CH$_3$)(C$_2$H$_3$O)}$_3$Cl]$_2$.TiCl$_4$. Such compounds were called **titanonium salts** by analogy with the corresponding **siliconium salts,** and **boronium salts**—*e.g. triacetylmethylacetonylsiliconium ferrichloride,* [Si{O.C(CH$_3$) : C(CH$_3$)(C$_2$H$_3$O)}$_3$Cl].FeCl$_3$; and *diacetylacetonyl-boronium hydrochloride,* [B{O.C(CH$_3$) : CH(C$_2$H$_3$O)}$_2$Cl].HCl. F. Wöhler, and E. A. Schneider obtained the addition products, TiCl$_4$.2HCy, with **hydrogen cyanide;** and TiCl$_4$.CyCl, with **cyanogen chloride.** A. Demoly, O. F. von der Pfordten, P. P. Bedson, H. R. Ellis, and A. Bertrand obtained TiCl$_4$.(C$_2$H$_5$)$_2$O, and 2TiCl$_4$.3(C$_2$H$_5$)$_2$O, with **ether;** E. A. Demarçay found that **alcohol** reacts with titanium tetrachloride, giving crystals of Ti(OC$_2$H$_5$)$_3$Cl.HCl, and that this reacts with sodium ethylate, forming **ethyl orthotitanate,** Ti(OC$_2$H$_5$)$_4$. G. Scagliarini also obtained complexes with other organic compounds. A. Benrath found that titanium tetrachloride in the presence of alcohol is slowly reduced by exposure to light; and A. Benrath and A. Obladen found that the photochemical reaction is accompanied by autoxidation resulting in the formation of hydrogen dioxide. Numerous complexes with organic compounds have been prepared. A. Benrath showed that titanium tetrachloride, in the presence of **oxalic acid, mandelic acid,** or **lactic acid,** is slowly reduced in light. N. Parravano and C. Mazzetti found that, at 900°, titanium tetrachloride is reduced by **iron,** forming a titanide.

The oxychlorides of titanium.—As previously indicated, the titanium di-chloride prepared by J. J. Ebelmen was shown by C. Friedel and J. Guérin to have been **titanous oxychloride,** or **titanyl chloride,** TiOCl, or Ti$_2$O$_2$Cl$_2$. J. J. Ebelmen obtained it in golden spangles as a by-product in preparing titanium trichloride. C. Friedel and J. Guérin passed a mixture of hydrogen and the vap. of titanium tetrachloride over white-hot titanium dioxide. The titanous oxychloride is mixed with some trichloride. E. A. Demarçay regarded it as an intermediate product in the chlorination of heated titanium dioxide by the vapour of carbon tetrachloride. The rhombic brownish-red or yellow plates appear red in transmitted light. The crystals, said C. Friedel and J. Guérin, are not immediately attacked by water, or even by dil. nitric acid. When, however, they are exposed for some time to the air they become white and are transformed into titanic acid. They are attacked by ammonia, which first blackens them, and afterwards they become white, still retaining their shapes; at the same time, there is an evolution of hydrogen. Heated in the air they are decomposed, giving off vapours of titanium tetrachloride, and leaving a residue of titanium dioxide.

L. Troost and P. Hautefeuille passed a mixture of oxygen and titanium tetra-chloride through a red-hot porcelain tube packed with porcelain shards. They obtained a white solid with a composition Ti$_2$O$_3$Cl$_2$, i.e. TiO$_2$.TiOCl$_2$. This product may be a chemical individual, titanium dioxide with adsorbed tetrachloride or chlorine; or **titanic oxydichloride,** i.e. *titanyl dichloride,* TiOCl$_2$, contaminated with titanium dioxide. F. Bourion obtained a yellow liquid supposed to be an oxychloride by passing a stream of chlorine mixed with the vap. of sulphur chloride, over ignited titanium dioxide. R. Weber, and V. Merz examined the product of the action of water on titanium tetrachloride, and found it contained variable proportions of titanium hydroxide and tetrachloride, and water. V. Auger pre-pared **titanium trihydroxychloride,** Ti(OH)$_3$Cl.2H$_2$O, or TiO$_2$.HCl.3H$_2$O, by evaporating a cold soln. of titanic chloride in conc. hydrochloric acid, over sul-phuric acid. The colourless, rhombohedral plates are decomposed in moist air.

O. F. von der Pfordten [4] regulated the mixing of conc. hydrochloric acid with the titanium tetrachloride. In this way, T. König and O. F. von der Pfordten obtained the three intermediate stages in the hydrolysis of titanium tetrachloride.

The first stage of the hydrolysis is represented by **titanium hydroxytrichloride,** $Ti(OH)Cl_3$, which is obtained by mixing the theoretical quantities of titanium chloride and 36 per cent. hydrochloric acid, the reaction being extremely energetic. It is a yellow, spongy, very deliquescent mass which dissolves very readily in water and alcohol with a hissing noise; it also dissolves in ether with a similar energetic reaction, but when more ether is added, a white deliquescent compound is precipitated. An aq. soln. is tolerably stable, but titanic acid is precipitated after continued boiling. When heated in the dry state, it is decomposed into titanic acid and titanic chloride; the same decomposition takes place when it is heated in a current of hydrogen or hydrogen chloride. The second stage of the hydrolysis is represented by **titanium dihydroxydichloride,** $Ti(OH)_2Cl_2$, and this is prepared by adding titanium tetrachloride to a slight excess of hydrochloric acid; by the action of titanium chloride on the calculated quantity of 36 per cent. hydrochloric acid; or by adding titanium tetrachloride to the requisite quantity of well-cooled water. It is a very voluminous, yellow, exceedingly deliquescent mass or a vitreous solid, according to the method of preparation. It is soluble in alcohol and ether, but a white compound is precipitated when a soln. is strongly diluted with absolute ether. Titanic acid separates when an aq. soln. is boiled. When heated in the dry state, it is rapidly decomposed, yielding titanic acid and hydrogen chloride. The third or penultimate stage of the hydrolysis is represented by **titanium trihydroxychloride,** $Ti(OH)_3Cl$, which is formed when either of the preceding compounds is allowed to remain for some time exposed to the air at the ordinary temp. Both compounds deliquesce, with evolution of hydrogen chloride, but at the end of about a month's time, they solidify. The product contains, approximately, two mols of water after remaining for two months over sulphuric acid. When placed in a desiccator containing phosphoric anhydride, it loses a mol of water in 14 days, and after a long time the anhydrous compound is obtained sometimes in a crystalline form. It is a white compound which is stable in the air, and far less readily soluble in water than either of the other two hydroxychlorides. In order to obtain a clear aq. soln. of the anhydrous compound, a few drops of hydrogen chloride must be added; titanic acid is precipitated from this soln. on boiling. It is insoluble in alcohol and ether. When heated, it yields titanic acid, hydrogen chloride, and water.

A. Mazzucchelli and E. Pantanelli prepared what they regarded as a salt of titanium trioxide, by treating a soln. containing hydrogen dioxide, titanium tetrachloride, and sodium chloride with alcohol. The composition corresponded with **sodium chloropertitanate,** $TiO_2Cl_2.2NaCl.9H_2O$. P. A. Bond and H. T. Beach found that with sulphur dioxide no compound is formed above the m.p. of sulphur dioxide, $-72°$; but the partially miscible liquids have a critical soln. temp. of $11.9°$.

The amminochlorides of titanium.—Three amminochlorides have been reported. H. Rose found that dry ammonia is rapidly absorbed by titanium tetrachloride, and there is a great evolution of heat. It is necessary to pass the gas for a long time with frequent agitation in order that the whole of the tetrachloride may be saturated with ammonia. The product can be preserved in well-stoppered bottles. If after standing some time the compound still smells of ammonia, it may be considered to have been saturated, but if it gives off white fumes, it should be again treated with ammonia. The analysis of the brownish-red product corresponded with **titanium tetramminotetrachloride,** $TiCl_4.4NH_3$. N. Whitehouse obtained the tetrammine as a canary-yellow powder in a similar manner. A. Rosenheim and O. Schütte obtained a white product with the same composition by keeping the hexammine over dry calcium chloride for some days; on the other hand, A. Stähler and H. Wirthwein said that the hexammine remains unaltered over freshly-ignited calcium chloride in the absence of air, but changes to titanic acid, ammonium chloride, and ammonia; $TiCl_4.6NH_3 + 4H_2O = Ti(OH)_4 + 4NH_4Cl + 2NH_3$, when kept over ordinary calcium chloride or in the presence of air. Accord-

ing to H. Rose, when the ammino-chloride is heated, a little ammonia is first evolved, then some ammonium chloride is given off, then a quantity of hydrogen chloride, and finally a sublimate of ammonium chlorotitanate. He called the residue metallic titanium, but it is really a titanium nitride. The ammino-chloride greedily absorbs moisture, and becomes white ; it is decomposed by water, forming a turbid liquid from which ammonia does not precipitate all the titanic acid, and from which hydrochloroplatinic acid precipitates about half the "ammonia." This indicates, said H. Rose, that the amminochloride "dissolves in water without decomposition, and not as a mixture of ammonium chloride and titanium oxide." He also found that when the amminochloride is heated with potassium or sodium, it is decomposed with vivid incandescence.

J. Persoz obtained a pale yellow powder by H. Rose's process, and the analysis corresponded with **titanium hexamminotetrachloride,** $TiCl_4.6NH_3$. A. Stähler and H. Wirthwein also obtained this compound as a saffron-yellow powder by passing the vapour of titanium tetrachloride in a stream of dried hydrogen into ammonia. A. Rosenheim and O. Schütte obtained the hexammine as a dark yellow powder by passing dry ammonia into a dry ethereal soln. of titanium tetrachloride cooled with ice ; on the other hand, A. Stähler and H. Wirthwein said that the octammine is produced when dry ammonia gas is passed into titanium tetrachloride suspended in absolute ether. The hexammine is very hygroscopic ; and, losing ammonia when exposed to the air, becomes paler in colour. For the behaviour in a desiccator over calcium chloride, *vide supra*. According to A. Stähler and H. Wirthwein, **titanium octamminotetrachloride,** $TiCl_4.8NH_3$, is obtained as just indicated, and also as a pale yellow powder when titanium tetrachloride is shaken for 12 hrs. with liquid ammonia. This compound gives up ammonia very readily on exposure to air, and it becomes white. It is decomposed by water with the separation of titanic acid ; and when either the hexammine or the octammine is extracted with liquid ammonia, ammonium chloride is removed, and dark yellow *titanamide*, $Ti(NH_2)_4$, remains. When the ammonia is removed by careful heating in vacuo, at 270°, *titanium chloronitride*, TiNCl, is formed.

Addition-compounds of titanium tetrachloride.—R. Weber passed the dried vapours from aqua regia over titanium tetrachloride, and obtained a compound **titanium dinitrosyl hexachloride,** $TiCl_4.2NOCl$. W. Hampe obtained the same product by the action of hyponitrous acid on titanium tetrachloride. The yellow crystal aggregate does not fume in air ; it is decomposed by water giving off nitric oxide. O. C. M. Davis reported that **titanium nitrogen sulphotrichloride,** $2TiCl_3.N_4S_4$, is formed in orange crystals when titanium tetrachloride is added to a soln. of nitrogen sulphide in chloroform ; whereas H. Wölbling obtained **titanium nitrogen sulphotetrachloride,** $TiCl_4.N_4S_4$, by the interaction of the components dissolved in carbon tetrachloride. The amorphous, brownish-red precipitate is insoluble in most solvents. It decomposes in moist air, and reacts very vigorously with water, alkali-lye, or nitric acid—sometimes with incandescence. Hydrochloric acid or alcohol splits the compound into its components.

O. Ruff reported the formation of **titanium sulphooctochloride,** $TiCl_4.SCl_4$, by dropping acid sulphur chloride into a soln. of titanium tetrachloride in sulphuryl chloride. The yellow, acicular crystals are very hygroscopic ; they are stable in an atm. of chlorine, but give off chlorine at ordinary temp. in an atm. of carbon dioxide. In a sealed tube with chlorine, the crystals melt at 62°–64° ; and sublime at 100°. They are soluble in sulphuryl chloride, chloroform, carbon disulphide, and petroleum ether. H. Rose, and R. Weber, obtained what they regarded as $2TiCl_4.SCl_4$, but O. Ruff believed that this is really $TiCl_4.SCl_4$. H. Rose made the compound by the action of sulphur chloride on titanium trichloride at ordinary temp. ; and by the action of chlorine on titanium sulphide. R. Weber sat. a mixture of titanium tetrachloride and sulphur chloride with dry chlorine, and warmed the product in a stream of chlorine so as to remove the excess of titanium tetrachloride or sulphur chloride. F. Bourion obtained it by the action of a

mixture of chlorine and sulphur chloride on titanium dioxide at a red heat; and
G. Darzeus and F. Bourion obtained it by the action of thionyl chloride on heated
titanium dioxide. F. Clausnizer obtained . **titanium sulphatotetrachloride,**
$TiCl_4.SO_3$, or $ClO_2.S.O.TiCl_3$, by dropping chlorosulphonic acid, $HO.SO_2Cl$, into
titanium tetrachloride; some hydrogen chloride was evolved. The mixture was
warmed on a water-bath. The resulting yellow powder is very hygroscopic and
fumes in moist air. R. Weber obtained **titanium selenium dioxyoctochloride,**
$TiCl_4.2SeOCl_2$, by dropping selenium oxydichloride into titanium tetrachloride.
The yellow powder does not fume in air; it is decomposed by moisture, and by
ammonia, and when heated, forms titanic oxide.

H. Rose showed that titanium tetrachloride absorbs phosphine, forming a brown
solid—**titanium phosphinotetrachloride**—which fumes on exposure to air. No
hydrogen chloride is evolved during the absorption, but when heated in a closed
vessel, hydrogen chloride, phosphine, and a lemon-yellow sublimate of **phos-
phonium chlorotitanate,** $3TiCl_4.2PH_4Cl$, are given off, and a copper-red residue
containing titanium remains. Titanium phosphinotetrachloride is decomposed by
water, hydrochloric acid, and by a soln. of alkali hydroxides or carbonates, or
ammonia—evolving phosphine with effervescence. A. Bertrand observed that
phosphorus trichloride unites directly with titanium tetrachloride, forming yellow
crystals of **titanium phosphorus heptachloride,** $TiCl_4.PCl_3$, which melts at $85.5°$.
J. Tuttscheff warmed a mixture of one mol of anhydrous titanium dioxide with three
mols of phosphorus pentachloride, and after keeping the mixture warm for a long
time to drive off the phosphoryl chloride, obtained **titanium phosphoric ennea-
chloride,** $TiCl_4.PCl_5$; R. Weber obtained it by saturating a mixture of phosphorus
trichloride and titanium tetrachloride with dry chlorine; and E. Wehrlin and
E. Giraud, by heating equimolar proportions of the constituents in a sealed tube
at $150°$. J. Gewecke obtained this compound by burning titanium phosphide
in an atm. of chlorine. The yellow product is very hygroscopic, and is decomposed
by water and alcohol, but absolute alcohol, according to J. Tuttscheff, dissolves
it without apparent decomposition; and phosphoryl chloride dissolves a small
proportion. It is soluble in dil. acids, but the soln. gradually gelatinizes.

R. Weber prepared **titanium phosphoryl heptachloride,** $TiCl_4.POCl_3$, by
dropping phosphoryl chloride into titanium chloride; and E. Wehrlin and
E. Giraud, by heating a mol of titanium dioxide and two mols of phosphorus penta-
chloride in a sealed tube. The colourless crystals are hygroscopic, and are decom-
posed by water, alcohol, and ether; they melt at $110°$, and boil at $140°$. O. Ruff
and R. Ipsen found that titanium tetrafluoride dissolves unchanged in cold phos-
phorus oxychloride, but at $30°$, a vigorous action takes place, and the chloride and
phosphorus oxyfluoride are produced; excess of phosphorus oxychloride gives a quanti-
tative yield of the yellow **titanium diphosphoryl decachloride,** $TiCl_4.2POCl_3$,
which melts at $107°$ and boils at $138°$.

Hydrochlorotitanic acid and the chlorotitanates.—According to O. F. von
der Pfordten, titanium tetrachloride dissolves in fuming hydrochloric acid with
the evolution of much heat, forming a deep yellow liquid, which becomes colourless
when diluted with water. W. von Kowalewsky measured the electrical con-
ductivity of the soln. and showed it to be highly probable that the yellow liquid
contains **hydrochlorotitanic acid,** H_2TiCl_6. A. Rosenheim and O. Schütte obtained
a yellow liquid containing, presumably, the same acid by treating titanic acid with
an alcoholic or ethereal soln. of hydrogen chloride. T. König and O. F. von der
Pfordten could not isolate the acid by the action of hydrogen chloride on titanium
tetrachloride alone or when dissolved in alcohol or ether.

A. Rosenheim and O. Schütte prepared dihydrated **ammonium chlorotitanate,**
$(NH_4)_2TiCl_6.2H_2O$, in yellow crystals by shaking a mixture of eq. quantities of
ammonium chloride and a hydrochloric acid soln. of titanium tetrachloride. The
crystals were washed with ether, and dried in vacuo over sulphuric acid. They
are very unstable in moist air, giving off hydrochloric acid, and becoming white.

V. Merz obtained the same salt. The compounds with pyridine, $(C_5H_5N)_2.H_2TiCl_6$; quinoline, $(C_9H_7N)_2.H_2TiCl_6$; and aniline, $(C_6H_5NH_2)_4.H_4TiCl_8$, were made by A. Rosenheim and O. Schütte.

P. Fireman obtained a double salt by heating titanium tetrachloride and ammonium chloride in a sealed tube ; and O. Ruff and F. Eisner heated titanium hexamminotetrachloride to the softening point of hard glass, and after the volatilization of most of the hexammino-salt, obtained a greenish-yellow sublimate consisting principally of titanium tetrachloride with one or two mols of ammonium chloride. The yellowish-white sublimate obtained by H. Rose by heating the tetrammino-salt—*vide supra*—contained $TiCl_4 + 3$ to $6NH_4Cl$.

§ 13. Titanium Bromides

Titanium forms the tri- and tetra-bromides; but the dibromide corresponding with the dichloride has not been obtained. A. Stähler [1] prepared hexahydrated **titanium tribromide,** or **titanous bromide,** $TiBr_3.6H_2O$, by electrolyzing a soln. of titanium tetrabromide in 20 per cent. hydrobromic acid, contained in the cathode compartment, using a platinum anode and a carbon cathode. The anode compartment contained 30 per cent. hydrobromic acid. When the cathode liquor has acquired a dark violet colour, and a portion gives a bluish-black precipitate with ammonia, the liquid is filtered and conc. in vacuo. When strongly cooled, or when a current of hydrogen bromide is passed through the liquid, a mass of dark violet crystals separates. The crystals are drained on asbestos, and dried on a porous tile over soda-lime. This salt is intermediate in stability between the corresponding chloride and iodide. It deliquesces in air to a brown, strongly-fuming liquid.

F. B. Duppa first made **titanium tetrabromide,** or **titanic bromide,** TiBr$_4$, by passing bromine vap. over an intimate mixture of titanium dioxide and carbon at a red heat. O. Ruff and F. Eisner made it by passing bromine vap. in a current of carbon dioxide over heated titanium or titanium carbide contained in a hard glass tube ; the product was purified by two distillations. T. E. Thorpe made it by the action of hydrogen bromide on titanium tetrachloride heated to a temp. below its b.p. At ordinary temp., titanium tetrabromide forms amber-yellow crystals, which, according to F. B. Duppa, have a sp. gr. 2·6 ; m.p., 39° ; and b.p., 230° ; W. Biltz and E. Keunecke gave 39° for the m.p. ; and T. E. Thorpe, 40° for the m.p., and 229° for the b.p. According to F. B. Duppa, the salt is very hygroscopic, and is hydrolyzed by water into hydrobromic and titanic acids ; and, added T. E. Thorpe, there is very little heat evolved when the compound dissolves in water, and the soln. is quite clear. A. Rosenheim and O. Schütte obtained **titanium hydroxytribromide,** Ti(OH)Br$_3$, by the action of a freshly prepared ethereal soln. of hydrogen bromide on hydrated titanium dioxide. The ethereal soln. furnishes yellow crystals which dissolve in water, but which are more readily decomposed than the corresponding chlorine compound. The salt is considered to be either the hydroxytribromide, or an addition product of this compound with ether. It was too unstable for analysis. They also made **titanium trihydroxybromide,** Ti(OH)$_3$Br, associated with 1½ mols of water or alcohol. The liquid obtained by the action of a soln. of hydrogen bromide in alcohol on hydrated titanium dioxide, when evaporated in vacuo, furnishes a white crystalline powder which, after washing with alcohol and ether, has the above composition. The product is stable in air ; it dissolves in cold water, forming a clear liquid which deposits titanic acid when boiled. W. Biltz and E. Keunecke found that the tetrabromide forms a *mono-sulphohydrate,* TiBr$_4$.H$_2$S, and a *disulphohydrate,* TiBr$_4$.2H$_2$S, with heats of formation 8·56 Cals. and 7·88 Cals. respectively.

A. Rosenheim and O. Schütte found that the tetrabromide dissolves in dry alcohol or dry ether, forming a yellow liquid. When hydrogen bromide is passed to sat. in the alcoholic or ethereal soln., a blood-red liquid is formed which probably contains **hydrobromotitanic acid,** H$_2$TiBr$_6$, analogous to the corresponding hydro-chlorotitanic acid. The acid has not been isolated, but **ammonium bromotitanate,** (NH$_4$)$_2$TiBr$_6$.2H$_2$O, was made by mixing ammonium bromide with a soln. of titanium bromide in hydrobromic acid ; dark red crystals separate on cooling. This salt is less stable than the corresponding chlorotitanate. The corresponding pyridine salt, (C$_6$H$_5$N)$_2$.H$_2$TiBr$_6$, was made in a similar manner.

O. Ruff and F. Eisner made **titanium octamminotetrabromide,** TiBr$_4$.8NH$_3$, by the action of ammonia gas on titanium tetrabromide at a low temp. When the ammonia is removed by careful heating in vacuo, *titanium bromonitride,* TiNBr, is formed (m.p. 39°, b.p. 230°) ; and, according to O. Ruff and O. Treidel, when washed with liquid ammonia, it furnishes an orange-yellow, insoluble product having a composition between 2Ti(NH$_2$)$_4$.TiBr$_4$.8NH$_3$ and 3Ti(NH)$_2$.TiBr$_4$.8NH$_3$.

C. Friedel and J. Guérin reported two mixed bromochlorides. One, obtained by the action of bromine on titanium dichloride, is considered to be **titanium di-chlorodibromide,** TiCl$_2$Br$_2$, and it boils at 176° ; the other, obtained by the action of bromine on titanium trichloride, was represented as **titanium bromotrichloride,** TiBrCl$_3$, and it boiled at 154°. There is no other evidence to show whether the products are chemical individuals or mixtures.

§ 14. Titanium Iodides

The three titanium di-, tri-, and tetra-iodides have been prepared. E. Defacqz and H. Copaux [1] found that titanium tetraiodide is readily reduced to the di-iodide by silver or mercury by arranging two porcelain boats in a porcelain tube—the anterior boat containing mercury and the posterior one titanium tetraiodide. The temp. was gradually raised to dull redness while a current of hydrogen passed through the tube. A sublimate of mercuric iodide and unchanged tetraiodide was formed in the cooled receiver, and fine black lamellæ of **titanium di-iodide,** TiI_2, were formed near the exit of the tube. The sp. gr. is 4·3 at 20°. The crystals are very hygroscopic, and are not acted on by organic solvents. They are dissolved by conc. hydrofluoric acid and by boiling hydrochloric acid, forming a blue soln. ; they are violently attacked by nitric and sulphuric acids with loss of iodine ; and are decomposed by water and aq. soln. of the alkalies. Titanium di-iodide forms additive compounds with dry ammonia and with hydrogen chloride. It is reduced by hydrogen at a white heat, but not at a red heat, giving amorphous titanium, which is very readily oxidized.

A. Stähler prepared hexahydrated **titanium tri-iodide,** or titanous iodide, $TiI_3.6H_2O$, by the electrolysis of a soln. of hydrated titanium dioxide in hydriodic acid, as in the case of the corresponding bromide. The liquid, when concentrated in vacuo, gives a violet, crystalline mass when hydrogen iodide is passed through the liquid. When exposed to the air, the crystals rapidly deliquesce to a brown, fuming liquid ; and the compound decomposes when kept in vacuo over soda-lime.

R. Weber made **titanium tetraiodide,** TiI_4, by passing the vapour of iodine over heated titanium, and removing the excess of iodine by heating the product in one leg of a sealed ∧-tube ; the iodine and some tetraiodide are condensed in the other leg. H. Moissan also made this compound by the action of iodine vapour on heated titanium. P. Hautefeuille prepared it by passing hydrogen iodide into warm titanium tetrachloride the temp. of which was gradually raised to the b.p. The product was repeatedly sublimed in a current of hydrogen in order to remove the excess of iodine. He also made the iodide by passing a mixture of hydrogen and the vapours of titanium tetrachloride and iodine through a tube heated to dull redness. Titanium tetraiodide collects in the cooler part of the tube, and is purified as in the previous process.

Titanium tetraiodide is a reddish-brown mass with a metallic appearance ; and, according to P. Hautefeuille, it melts at 150° to a yellowish-brown liquid which remains liquid even when cooled below 100°, but is eventually solidified, forming octahedral crystals which, after some days, form prismatic plates. W. Biltz and E. Keunecke gave 143·5° for the m.p. P. Hautefeuille found that the vap. press. of the solid is appreciable at ordinary temp., and it boils a little over 360°, forming an orange vapour. It can be distilled unchanged, the vap. density, 18·054 at 440°, corresponding with a mol. wt. of 520, when that of TiI_4 is 556. The solid fumes in air, and it is combustible, burning to iodine and titanium dioxide. It rapidly dissolves in water with the evolution of less heat than is the case with the tetrachloride. The aq. soln. becomes brown in air ; and it deposits titanic acid owing to hydrolysis. The dark red liquid obtained when the tetraiodide dissolves in fuming hydriodic acid was assumed by A. Rosenheim and O. Schütte to contain **hydriodotitanic acid,** H_2TiI_8, but the acid and its salts—the *iodotitanates*—were too unstable to be isolated. W. Biltz and E. Keunecke observed that titanium tetraiodide does not form a sulphohydrate with hydrogen sulphide.

§ 15. The Titanium Sulphides

Titanium furnishes three sulphides—the mono-, sesqui-, and di-sulphides. A. Blair and P. W. Shimer [1] observed crystals of a titanium sulphide in commercial iron. H. Rose said that in preparing the disulphides by the process described below, some black sulphide—probably **titanium monosulphide,** TiS—is formed at the same time. O. F. von der Pfordten made the monosulphide by heating one of the higher sulphides in a platinum tube at a temp. above the softening temp. of glass; A. E. van Arkel and J. H. de Boer, by passing the vapours of the tetrachloride over a heated tungsten filament; and T. E. Thorpe, by heating the sesquisulphide in a current of hydrogen. Titanium monosulphide is a reddish solid with a metallic appearance recalling that of bismuth. E. Wedekind obtained the value $5\cdot4\times10^{-6}$ for the magnetic susceptibility of the monosulphide. It is stable in air at ordinary temp., but glows when heated, forming sulphur and titanium dioxides. It is not appreciably affected by water, or by hydrochloric, hydrofluoric, and dil. sulphuric acids; it is dissolved by conc. sulphuric acid; it is not affected by alkali-lye; and it is slowly oxidized by dil. nitric acid, and by aqua regia. P. Pipereaut and A. Helbronner obtained pigments from mixtures of titanium sulphide, zinc sulphate, and barium sulphate.

H. Rose assumed that he made titanium disulphide by the action of carbon disulphide on red-hot titanium dioxide, but J. J. Ebelmen showed that the product has not a constant composition, and that its composition approaches more nearly to that of **titanium sesquisulphide,** Ti_2S_3, than it does to the disulphide, TiS_2. T. E. Thorpe made the sesquisulphide by strongly heating powdered titanium dioxide in a mixture of not quite dry hydrogen sulphide, and the vapour of carbon disulphide. The green colour of Thorpe's product was attributed by O. F. von der Pfordten to the presence of vanadium; and he prepared the sesquisulphide by heating the disulphide in a current of nitrogen or hydrogen, at a lower temp. than is needed to produce the monosulphide : $2TiS_2=Ti_2S_3+S$. N. Whitehouse employed a similar process. E. A. Schneider obtained it by passing a mixture of hydrogen and sulphur vapour over red-hot titanium nitride. Titanium sesquisulphide is a greyish-black crystalline powder which is stable in air, and in contact with water, alkali-lye, dil. hydrochloric acid, or dil. sulphuric acid; it is soluble in conc. sulphuric acid, forming a green soln.; it is not oxidized by dil. nitric acid, but furnishes a green soln. with conc. nitric acid. Hydrofluoric acid does not react at the temp. of a water-bath. It glows when heated in air, and is oxidized.

H. Rose prepared a dark green mass of what he supposed to be **titanium disulphide,** TiS_2, by pressing moistened titanium dioxide into lumps; and, after drying, igniting them in a stream of the vapour of carbon disulphide in a porcelain tube. N. Whitehouse also passed carbon disulphide over red-hot titanium dioxide to make the disulphide. P. Berthier also obtained the disulphide in bronze-yellow scales by strongly heating a mixture of rutile, sodium carbonate, and sulphur, pressed into a crucible, and covered with a layer of charcoal. The product was coarsely pulverized, lixiviated with water, treated with sulphuric acid, and again washed with water. The product was necessarily crude and impure. J. J. Ebelmen obtained the disulphide of a high degree of purity by passing a mixture of hydrogen sulphide and the vapour of titanium tetrachloride through a heated tube. If the temp. be not too high, the interior of the tube will be lined with yellow scales. O. Ruff and R. Ipsen used titanium tetrafluoride in place of the tetrachloride and obtained the brown disulphide. O. F. von der Pfordten said that the reaction : $TiCl_4+2H_2S=TiS_2+4HCl$, occurs only at a very high temp.; in the cold, the reaction is represented : $TiCl_4+H_2S=2HCl+S+TiCl_2$ (*q.v.*); and at intermediate temp., *titanium sulphochloride*, TiSCl, is formed. To obtain a

pure product by J. J. Ebelmen's process, it is necessary to free the hydrogen sulphide from oxygen by bubbling it through a soln. of a chromous salt, and from moisture by scrubbing the gas with phosphorus pentoxide.

The titanium disulphide obtained by J. J. Ebelmen was in the form of yellow, lustrous scales resembling mosaic gold. O. Ruff and R. Ipsen found that it sublimes rather less readily than the tetrafluoride. O. F. von der Pfordten showed that it is stable in air; J. J. Ebelmen said that in moist air it smells feebly of hydrogen sulphide, but O. F. von der Pfordten said that it is not decomposed by water. H. V. Regnault found that it easily decomposes when heated in a current of steam, forming hydrogen sulphide, hydrogen, sulphur, and titanium dioxide. O. F. von der Pfordten showed that the disulphide readily burns when heated in air, forming titanium and sulphur dioxides; and a mixture with potassium nitrate detonates when heated. Dry chlorine converts it into sulphur chloride and titanium tetrachloride, and some admixed titanium dioxide may remain unattacked. H. Rose, and J. J. Ebelmen found that the disulphide dissolves in hydrochloric acid with the evolution of hydrogen sulphide. J. J. Ebelmen said that the disulphide dissolves in dil. sulphuric acid, and also in nitric acid, leaving very little residue. H. Rose, however, found that warm nitric acid dissolved very little of his product, since titanium dioxide and sulphuric acid were formed. O. F. von der Pfordten observed that when heated in a stream of carbon dioxide, the sulphur is separated, and the titanium forms the dioxide. H. Rose said that with an aq. soln. of potassium hydroxide, insoluble potassium titanate and soluble potassium sulphide are formed: $TiS_2 + 6KOH = K_2TiO_3 + 2K_2S + 3H_2O$. The disulphide is insoluble in potassium hydrosulphide or sulphide, and therefore possesses no thioanhydridic properties.

O. F. von der Pfordten's titanium thiochloride, and the compounds of titanium tetrachloride with sulphur and sulphuryl chlorides, have been previously described. N. S. Maskelyne [2] found golden-yellow, octahedral crystals of what was considered to be a *calcium titanium oxysulphide* in the oldhamite and augite found in a meteorite which fell in Busti, India. It was named *osbornite*—after G. Osborne. A similar substance was prepared by J. W. Mallet by heating zircon with lime and alumina.

§ 16. The Titanium Sulphates

Titanium forms mono-, sesqui-, and di-sulphates, as well as a number of basic and double or complex sulphates. In this respect, titanium is in marked contrast with silicon, and germanium. According to A. Stähler and H. Wirthwein,[1] **titanium monosulphate,** $TiSO_4$, is formed by the evaporation of a soln. of titanium in sulphuric acid; and not, as stated by E. Glatzel, the violet octohydrated **titanium sesquisulphate,** or **titanous sulphate,** $Ti_2(SO_4)_3.8H_2O$. J. J. Ebelmen reported
that violet crystals of a titanium sulphate are produced by dissolving titanium trichloride in sulphuric acid, and evaporating the soln. in vacuo over caustic lime. Analysis showed rather more sulphuric acid than corresponded with $Ti_2(SO_4)_3$. The aq. soln. deposited titanic acid when boiled. F. Wöhler and H. St. C. Deville prepared a similar salt. A. Stähler and H. Wirthwein prepared the sesquisulphate by repeatedly evaporating a conc. soln. of the chloride with dil. sulphuric acid in vacuo at 60°. The crystalline mass after washing with acetic acid, and ether, has the composition $3Ti_2(SO_4)_3.H_2SO_4.25H_2O$, **titanous hydrosulphate.** The same salt may be obtained as a violet crystalline powder by heating titanium tetrachloride with sulphuric acid until fuming ceases, dissolving the syrupy sulphate in 50 per cent. sulphuric acid, and electrolytically reducing the soln. for 5 to 6 hrs. The hydrosulphate dissolves slowly in water, forming a violet soln. When heated, the salt first gives off water, and then sulphuric acid, becoming at the same time green in colour. At a low red-heat, sulphur dioxide is evolved, and titanium dioxide remains. The anhydrous sesquisulphate, $Ti_2(SO_4)_3$, is deposited, after the protracted evaporation of the violet soln. of titanium sesquisulphate, with dil. sulphuric acid in absence of air. It is a green, crystalline powder insoluble in water, alcohol, ether, or conc. sulphuric acid, but soluble in dil. sulphuric or hydrochloric acid giving a violet soln. for the reducing action—*vide supra*, the trichloride. W. H. Evans examined the effect of current density, concentration of soln. and temp. on the electrolytic reduction of titanic sulphate, and found that good yields of titanous sulphate could be obtained without the use of a diaphragm. If the current density at the anode is kept fairly high, oxygen is evolved without effecting any marked oxidation of the titanous salt. The yield diminishes rapidly with increase of current density. Rise of temp. increases the yield. The electrolytic reduction of a soln. of titanium disulphate in sulphuric acid was further studied by B. Diethelm and F. Förster.

The properties of titanium sesquisulphate are closely analogous with those of the corresponding vanadium salt. The hydrosulphate can also be called *titanosulphuric acid* or *sulphatotitanic acid* because corresponding double or complex salts have been made. According to A. Stähler and H. Wirthwein, **ammonium titanous sulphate,** $3Ti_2(SO_4)_3.(NH_4)_2SO_4.18H_2O$, is obtained by boiling a mol of a soln. of the hydrosulphate with 2·5 mols of ammonium sulphate. The pale blue crystals are washed with water, alcohol, and ether. The crystals are stable in air. The salt is insoluble in water and sulphuric acid, but soluble in hydrochloric acid. Boiling sulphuric acid decomposes the salt into its components. By replacing the ammonium sulphate with rubidium sulphate, **rubidium titanous sulphate,** $3Ti_2(SO_4)_3.Rb_2SO_4.24H_2O$, is formed; and its properties are like those of the ammonium salt. A salt of a different type, a **sodium titanous sulphate,** $Na_2SO_4.Ti_2(SO_4)_3.5H_2O$, or $NaTi(SO_4)_2.2\frac{1}{2}H_2O$, has been prepared by P. and H. Spence, by the electrolytic reduction of titanium sulphate in the presence of sulphuric acid, with the addition of sodium sulphate, after which the solution thus formed is evaporated. The salt is lilac in colour, easily soluble in water, and forms a strong reducing agent. E. Knecht added that the salt is insoluble in alcohol, and it is a convenient source of a titanous salt as a reducing agent. H. Spence and co-workers found that a solid titanium salt of a mineral acid, such as titanous sodium sulphate, is obtained by adding a suitable organic acid (*e.g.* citric acid) or salt, and preferably also aluminium sulphate, to a soln. of the salt, and concentrating the soln., if necessary, until the titanium sodium sulphate separates. Prepared in this way, the soln. of the double salt has little or no tendency to deposit titanium dioxide during use, *e.g.* in discharge dyes. T. Nakazono obtained a soln. of the salt by reduction with zinc amalgam in $4N$-H_2SO_4. A. S. Russell found that the soln. in $4N$-H_2SO_4 can be kept for 12 hrs. in a burette exposed to air, without losing its strength—*vide supra*, titanous chloride.

A. Piccini was unable to obtain *ammonium titanous alum*, $(NH_4)_2SO_4,Ti_2(SO_4)_3.$ $24H_2O$, that is, **ammonium sulphatotitanite,** $(NH_4)Ti(SO_4)_2.12H_2O$, and *potassium*

titanous alum, $K_2SO_4.Ti_2(SO_4)_3.24H_2O$, that is, **potassium sulphatotitanite,** $KTi(SO_4)_2.12H_2O$, in a crystalline form ; and he considered that cæsium sulphate is the best salt to employ for determining whether a sesquioxide is capable of forming alums. He obtained *cæsium titanous alum*, $Cs_2SO_4.Ti_2(SO_4)_3.24H_2O$, that is, **cæsium sulphatotitanite,** $CsTi(SO_4)_2.12H_2O$, by dissolving precipitated titanic acid in a slight excess of dil. sulphuric acid, adding the theoretical quantity of a cold soln. of cæsium sulphate, and then subjecting the mixture to electrolysis, using as a diaphragm an ordinary porous cylinder ; the soln. at the negative pole quickly becomes violet and deposits crystals of the alum. It is purified in an atm. of carbon dioxide by recrystallization from water acidified with sulphuric acid, when it forms pentagonal, hemihedral, bright violet crystals belonging to the cubic system ; it is very sparingly soluble in cold water, more so in hot water, and the soln. quickly becomes turbid on exposure to the air, with precipitation of titanic acid. When heated in the air, it is oxidized, giving off vapours of water and sulphuric acid. The corresponding *rubidium titanous alum*, $Rb_2SO_4.Ti_2(SO_4)_3.24H_2O$, that is, **rubidium sulphatotitanite,** $RbTi(SO_4)_2.12H_2O$, was obtained in a similar manner. It crystallizes in transparent, bright red crystals belonging to the cubic system ; and is very similar to the cæsium salt, but is more soluble in water.

Trihydrated titanium disulphate, $Ti(SO_4)_2.3H_2O$, was reported by E. Glatzel [2] to be a yellow amorphous mass obtained by evaporating a soln. of the sesqui-sulphate oxidized with nitric acid. There are grave doubts if this product is really the normal disulphate. In opposition to P. Faber, L. and P. Wöhler and W. Plüdde-mann were unable to get a product with a ratio higher than $SO_3 : TiO_2 = 1 : 1$ by heating titanium dioxide with sulphuric acid. A soln. of titanium dioxide in sulphuric acid is assumed to contain titanium disulphate, $Ti(SO_4)_2$. W. Ramsay and F. L. Usher claimed to have degraded titanium to carbon by the action of radium emanation on a soln. of titanium sulphate. A. Benrath found that titanium sulphate is photochemically reduced in the presence of alcohol, or oxalic acid. The reaction was also studied by A. Benrath, and A. Obladen. L. Wöhler and co-workers measured the vapour tension of the basic titanium sulphates at different temp. For the electro-reduction of titanium sulphate, *vide* titanic chloride. Quite a number of basic titanium sulphates have been reported. Probably some of them are mixtures and not chemical individuals, and represent different stages in the hydrolysis of titanium disulphate. Their composition seems to depend on the temp. and conc. of the mother-liquid. The question will be settled by an application of the phase rule. The existence of hydrated forms of the following seems likely :

$$Ti{<}{\begin{matrix}SO_4\\SO_4\end{matrix}} \qquad O{<}{Ti}{<}{\begin{matrix}SO_4\\SO_4\\SO_4\end{matrix}} \qquad O{=}Ti{=}SO_4$$

<div align="center">
Titanium disulphate,   Titanium oxytrisulphate,   Titanyl sulphate,
$Ti(SO_4)_2$ $Ti_2O(SO_4)_3$ $TiOSO_4$
</div>

According to M. Blondel, the first basic sulphate, trihydrated **titanium oxytri-sulphate,** $Ti_2O(SO_4)_3.3H_2O$, is obtained by heating a soln. of titanium dioxide in conc. sulphuric acid in a sealed tube at 120°. The salt appears as a mass of silky crystals which are soluble in water acidified with hydrochloric acid. On raising the temp. to 225°, the mass changes into rhomboidal crystals of the second basic sulphate —anhydrous **titanyl sulphate,** $TiOSO_4$—which are slowly decomposed by water into a basic sulphate and sulphuric acid. By maintaining the soln. at 225°, the whole of the titanium present can be separated in this form. V. Merz made it as a white powder by evaporating a sulphuric acid soln. of titanic acid to dryness ; removing the excess of sulphuric acid by allowing the mass to stand on a porous tile ; and drying the residue at 350°–400°. The product is slowly decomposed by water. The hydrolysis of titanic sulphate has been studied by H. Rose, R. Weber, C. F. Rammelsberg, and R. Ruer ; and the results compared with those

of stannic chloride by R. Lorenz, W. Mecklenberg, and L. Kayser. K. Someya studied the reduction of titanic sulphate by lead and zinc amalgams. L. and P. Wöhler and W. Plüddemann found the vap. press., P mm., of two products, $TiO_2.SO_3$, and $2TiO_2.SO_3$, at 0°, to be

				$TiO_2.SO_3$, or $TiOSO_4$				$2TiO_2.SO_3$			
0°	.	.	.	545°	560°	592°	595°	524°	574°	590°	610°
$P°$	.	.	.	24	38	92	300	15	60	214	592

C. Weizmann and J. Blumenfeld made the salt from the titaniferous ore. The *monohydrate*, $TiOSO_4.H_2O$, appears to have been made by J. J. Berzelius, and H. Rose, by digesting finely powdered titanium dioxide in a mixture of sulphuric acid and water (2 : 1) until the whole of the water is expelled. The temp. is then raised, but not to redness, in order to drive off the excess of sulphuric acid. H. Rose also obtained this sulphate, from a soln. of hydrated titanium dioxide or acid potassium titanite in dil. sulphuric acid. H. Rose, and V. Merz precipitated it by adding sulphuric acid to a dil. soln. of titanium in hydrochloric acid. V. Merz, and A. Ditte obtained a similar product by thoroughly washing the first basic sulphate, $Ti_2O(SO_4)_3$. H. Rose said that the white product reddens moist litmus; and when dried, rapidly absorbs moisture. It dissolves in an excess of sulphuric acid, and in an excess of a hydrochloric acid soln. of titanium. When ignited, it furnishes titanium dioxide. A. Ditte, and M. Blondel made the *dihydrate*, $TiOSO_4.2H_2O$, by diluting a soln. of titanium dioxide in conc. sulphuric acid; the liquid at any temp. above 100°, deposits this salt in long needles which are readily soluble in water. A. Rosenheim and O. Schütte prepared the *pentahydrate*, $TiOSO_4.5H_2O$, as a white amorphous mass by boiling titanic acid with alcoholic sulphuric acid, evaporating off the alcohol, and precipitating with ether. The same hydrate was always obtained under wide variations in the experimental conditions.

M. Blondel also reported three basic sulphates with $TiO_2 : SO_3 : H_2O = 2 : 1 : n$; $7 : 2 : n$; and $5 : 1 : 5$. He said that if one part of titanium dioxide be dissolved in 2 parts of conc. sulphuric acid, and water be added to the extent of $1\frac{1}{2}$ times the weight of the soln., the liquid deposits sulphates, the composition of which varies with the temp. of deposition ; those formed at 100° correspond with the formula $2TiO_2.SO_3.nH_2O$, and those at 130°, with $7TiO_2.2SO_3.nH_2O$. Soln. of titanium dioxide in conc. sulphuric acid, when dil. with rom 2 to 10 times their weight of water and heated, deposit various sulphates at temp. below 175°, but above this temp., the anhydrous dioxide crystallizes out; if, however, the soln. be strongly dil. (with 100 to 1000 parts of water) at ordinary temp., the compound $5TiO_2.SO_3+5H_2O$ is obtained, whilst at 100°, the deposit consists of the dioxide with traces of sulphuric acid which cannot be removed by washing. H. Geisow made a product corresponding with $4TiO_2.3SO_3$ by gradually heating a soln. of titanium dioxide in conc. sulphuric acid to 340°, and holding it at that temp. for 18 hrs., when the weight remained constant. When heated to 420°–430°, the composition was $2TiO_2.SO_3$.

F. Wöhler made anhydrous **potassium titanic sulphate,** $K_2SO_4.Ti(SO_4)_2$, by dissolving titanium dioxide in molten potassium hydrosulphate. The glassy mass became opaque in contact with water, and titanic acid separates as it dissolves. C. M. Warren digested the glass with conc. sulphuric acid, and evaporated most of the acid at a low temp. The crystalline mass was washed and the remaining crystals corresponded with $K_2SO_4.Ti(SO_4)_2$. The crystals are decomposed by much water. A. Rosenheim and O. Schütte investigated this subject. R. F. Weinland and H. Kühl made **calcium titanic sulphate,** $CaSO_4.Ti(SO_4)_2$, **strontium titanic sulphate,** $SrSO_4.Ti(SO_4)_2$; and **barium titanic sulphate**, $2BaSO_4.3Ti(SO_4)_2$, by mixing soln. of titanium dioxide in conc. sulphuric acid with soln. of the appropriate sulphates in the same solvent and concentrating. The calcium and strontium salts crystallize in small, well-formed, colourless, lustrous cubes ; the barium salt in slender needles. All the salts are decomposed by water with precipitation of titanic acid. They may be derived from complex titanic acids in which part of the oxygen is replaced by SO_4.

M. Blondel reported the formation of cubic crystals of **ammonium titanium oxysulphate,** $(NH_4)_2SO_4.2TiO_2.SO_3.H_2O$, when a sulphuric acid soln. of titanium dioxide diluted with slightly ammoniacal water, is allowed to evaporate in vacuo. The crystals show tetrahedral hemihedrism ; they effloresce in air, and are slowly decomposed by water. A. Rosenheim and O. Schütte prepared white needles of **ammonium titanyl sulphate,** $(NH_4)_2SO_4.TiOSO_4.H_2O$, by adding a conc. soln. of ammonium sulphate to a soln. of titanium dioxide in conc. sulphuric acid. The salt is very soluble in water, but it cannot be crystallized from its aq. soln. without decomposition. F. M., D. D., and H. Spence made the ammonium salt by a process analogous to that used for **potassium titanyl sulphate,** $K_2SO_4.TiOSO_4$, namely, by fusing titanium dioxide with potassium hydrosulphate, extracting with 10 per cent. sulphuric acid, and evaporating the soln. until its sp. gr. is 1·4, when crystallization occurs. The titanium dioxide was digested with an excess of hot sulphuric acid ; and the soln. mixed with potassium sulphate $(TiO_2 : K_2SO_4=1 : 1)$ and the soln. conc. for crystallization. These salts are soluble in cold water, but titanic acid gradually separates from their soln. A. Rosenheim and O. Schütte found that **potassium trititanyl pentasulphate,** $2K_2SO_4.3TiOSO_4.10H_2O$, is deposited in colourless needles when a conc. aq. soln. of potassium sulphate is added to a sat. soln. of titanic acid in conc. sulphuric acid. F. M., D. D., and H. Spence made the **sodium titanyl sulphate,** $Na_2SO_4.Ti(SO_4)_2$, in a manner similar to that employed for the potassium salt. A. Mazzucchelli and E. Pantanelli prepared a series of salts by the addition of alcohol to a soln. containing titanium sulphate, hydrogen dioxide, and an alkali sulphate in rather less amount than corresponding with the ratio $TiO_2 : M_2SO_4$. The salts are readily dissolved by water, and are supposed to be derivatives of titanium trioxide. In this way, **ammonium sulphatopertitanate,** $TiO_2(NH_4SO_4)_2.nH_2O$; **lithium sulphatopertitanate,** $TiO_2(LiSO_4)_2.7H_2O$; **sodium sulphatopertitanate,** $TiO_2(NaSO_4)_2.10H_2O$; and **potassium sulphatopertitanate,** $TiO_2(KSO_4)_2.7H_2O$, were obtained.

§ 17. Titanium Carbonates, Nitrates, and Phosphates

There is no evidence that *titanium carbonate* has yet been prepared. J. J. Berzelius [1] reported the formation of an **ammonium titanic carbonate** in soln., for, when an acid soln. of titanic acid is dropped into a large excess of an aq. soln. of ammonium carbonate, the precipitate which first forms is re-dissolved, and the soln. deposits titanic acid when boiled. Similarly, **potassium titanic carbonate,** but titanic acid is not precipitated by boiling the soln. ; this does occur, however, if ammonium chloride be present when the soln. is boiled. Many double salts with organic acids—formic, oxalic, and tartaric acids—have been prepared. V. Auger found that when titanic chloride is added to a mixture of potassium hydrocarbonate and its aq. soln., as much as 2000 mgrms. of titanium salt per 100 c.c. may remain in soln., but 1300 mgrms. are precipitated in a few hours. A double carbonate is considered to be present in the more conc. soln.

H. Rose prepared a soln. containing presumably **titanium nitrate** by dissolving hydrated titanium dioxide or potassium titanate in nitric acid. V. Merz evaporated the liquid over caustic lime, and obtained crystals of a basic salt, **titanium oxynitrate,** with the composition $5TiO_2.N_2O_5.6H_2O$. Complex or double salts have not yet been prepared.

H. Rose obtained what he regarded as a *titanium phosphite* by adding an aq. soln. of phosphorus trichloride to an aq. soln. of titanium chloride, and neutralizing with ammonia. When the white precipitate is heated in a retort, hydrogen and phosphorus vap. are evolved, and a black residue containing titanium dioxide remains. H. Rose also precipitated what he called *titanium phosphate* by adding phosphoric acid to a soln. of titanium dioxide in hydrochloric acid. The white, flaky precipitate is soluble in an excess of either phosphoric acid or titanium chloride ; and it dries to a gummy mass. L. Ouvrard obtained a product with the composition $TiO_2.P_2O_5$, which can be regarded as **titanyl metaphosphate,** $TiO(PO_3)_2$, by dissolving titanium dioxide in molten potassium or sodium metaphosphate, and slowly cooling the product. P. Hautefeuille and J. Margottet dissolved hydrated titanium dioxide in orthophosphoric acid, at a temp. when the dehydration begins. The octahedral crystals were assumed to have the composition $TiO_2.P_2O_5$. E. Wehrlin and E. Giraud obtained the same product from titanium chlorotriethoxyphosphate, $TiCl(OC_2H_5)_3.3H_3PO_4$. V. Merz obtained a titanium phosphate of the composition $2TiO_2.P_2O_5.3H_2O$, by precipitating a soln. of titanium chloride with a soluble phosphate, and thoroughly washing the product. *Vide* titanium chloride for a number of *chlorophosphates.*

According to L. Ouvrard, when titanium dioxide is fused with a large excess of potassium metaphosphate, octahedral crystals of $TiO_2.P_2O_5$ are formed ; with a higher proportion of titanic oxide, **potassium triphosphatotitanate,** $K_2O.4TiO_2.$ $3P_2O_5$, or $KTi_2(PO_4)_3$, is obtained in small, highly refractive, almost cubic crystals, isomorphous with the corresponding sodium salt. Potassium pyrophosphate or orthophosphate yields **potassium oxyphosphatotitanate,** $K_2O.2TiO_2.P_2O_5$, or $KTiOPO_4$, in biaxial crystals, probably monoclinic, but closely resembling regular octahedra. With other proportions of titanic oxide, acicular crystals of rutile are obtained, and these crystals are formed instead of the double phosphate if an excess of potassium chloride is present. J. J. Berzelius noted that titanium dioxide dissolves in molten microcosmic salt or sodium metaphosphate, forming a clear glass ; and G. Rose noted that the sat. soln. furnishes crystals of anatase. L. Ouvrard obtained crystals of **sodium titanium phosphate,** $Na_2O.4TiO_2.3P_2O_5$, or $Ti_3(PO_4)_4.TiNa_2(PO_4)_2$, from the soln. of titanium dioxide in molten sodium metaphosphate. A. Knop regarded the product as $3TiO_2.P_2O_5$, and G. Wunder and L. Ouvrard, as $Na_2O.4TiO_2.3P_2O_5$. R. Brauns supposed that some titanium sesquioxide was present. The rhombohedral crystals were supposed by G. Wunder

to be isomorphous with the corresponding tin compound. G. Rose regarded the crystals as tetragonal; A. Knop, rhombic. According to G. Wunder, the salt is decomposed when fused with an excess of sodium carbonate, and when the product is extracted with water, sodium titanate remains undissolved. L. Ouvrard found that when titanium dioxide is dissolved in fused sodium pyrophosphate or orthophosphate, crystals of $6Na_2O.3TiO_2.4P_2O_5$, are formed in macled, striated prisms with longitudinal extinctions. G. Saring reported **potassium calcium phosphatotitanate,** $Ca_3(PO_4)_2(CaO)_2(K_2O)_2TiO_2$, analogous with the corresponding silicate.

P. Faber obtained a voluminous yellow precipitate of **titanium trihydroxyorthophosphate,** $(HO)_3TiPO_4$, by adding sodium phosphate to a sulphuric acid soln. of pertitanic acid ; and also by adding ammonium phosphate to an ammoniacal soln. of pertitanic acid. The product in each case was washed with acetic acid in which it is sparingly soluble. It is, however, soluble in hydrochloric, nitric, sulphuric, and phosphoric acids, in soln. of potassium hydroxide, ammonia, and ammonium carbonate or phosphate. It decomposes when heated to a high temp. P. Faber assumed that the product contained sexivalent titanium :
A. Mazzucchelli and E. Pantanelli could not verify P. Faber's observation, but they obtained instead **sodium phosphatopertitanates,** $Na_2O.TiO_3.P_2O_5.3H_2O$, and $O : TiO_2.P_2O_5.Na_2O_2.24H_2O$. M. Billy made an insoluble *pertitanic phosphate* by mixing soln. of acid titanium sulphate, sodium phosphate, and hydrogen dioxide, and precipitating with sodium acetate. The precipitate lost oxygen during the washing.

CHAPTER XLII

ZIRCONIUM

§ 1. History of Zirconium

THE bluish-violet mineral **hyacinth** (or jacinth)—from ὑάκινθος, a (lily) flower—has been known very many years as an inferior gem-stone. The minerals *sacondios*, *chrysolithos*, *melichrysos*, *crateritis*, and *hyacinthus*, mentioned in Pliny's *Historiœ naturalis* (**37**. 40–56), may possibly have been related to the hyacinth. The *lyncurium*, mentioned by Theophrastus, in his Περὶ Λίθων, about 300 B.C., was not known to Pliny (**36**. 13). The statements that the *lyncurium* was used for engraved signets, that it was electrified by friction, and that it was often amber-coloured, are the sole evidence for assuming that zircon was in question. Intagli of zircon are common among ancient gems. The different varieties of the genera range in tint from yellow, brown, to red, and they may also be colourless, green, rose-red, or violet. The name hyacinth is now usually confined to reddish varieties. Hyacinths were mentioned by many writers in the Middle Ages.[1] G. Agricola called it *jacinth ;* A. Cronstedt, *jargon ;* J. G. Wallerius, *clarus hyalinus ;* J. B. L. Romé de l'Isle, *diamant brut* or *jargon de Ceylon ;* F. de St. Fond said that *le nom d'hyacinte orientale* was applied to oriental rubies of an orange-red colour, and added, *il est usage d'appeler* **jargon** *toute pierre de peu de valeur, qui imite l'éclat de diamant sans avoir la dureté.* In the eighteenth century, colourless jargons were supposed to be inferior or imperfect diamonds, and, being common in the Matura district, Ceylon, were called *Matura diamonds.* J. B. L. Romé de l'Isle proved *jargon de Ceylon* to be a distinct mineral species which A. G. Werner designated **zircon,** or *silex circonius*—presumably from the Arabian *zerk*, a precious stone. According to J. Prinsep, and F. R. Mallet, the Singalese jewellers called the mineral *turmali.*

Near the end of the eighteenth century, M. H. Klaproth,[2] in the course of a *Chemische Untersuchung des Zircons*, fused specimens of yellowish-green and red zircon from Ceylon, with sodium hydroxide, and extracted the cold mass with hydrochloric acid. Potassium carbonate was added to the soln., and the precipitate filtered off and washed. The precipitate was again digested with sulphuric acid, and the soln. evaporated to dryness ; the residue was digested with sulphuric acid and the silica filtered off. The filtrate was tested for lime, magnesia, and alumina, but none was found. The liquid, however, did give a precipitate with potassium carbonate, which, unlike precipitated alumina, did not dissolve in alkali-lye, and, unlike precipitated magnesia, did not effervesce with acids. The precipitate, indeed, behaved like no other known substance, and accordingly, M. H. Klaproth stated :

I feel myself justified in concluding this precipitate to be a distinct and simple earth previously unknown. I propose to call it *Zirkonerde—terra circonia*—until it may be found in other minerals, or possessed of other properties which may suggest a more appropriate denomination.

The average of M. H. Klaproth's analyses of the zircon yielded: Silica, 31·5 ; iron oxide, 0·5 ; zircon earth, 68·0 per cent. M. H. Klaproth further found that a sample of hyacinth from Ceylon yielded on analysis : Silica, 25·0 ; iron oxide, 0·5 ; and zircon earth, 70·0 per cent. This result caused some surprise, because the standard analyses of this mineral by T. Bergman [3] indicated : Silica, 25 ; alumina,

40 ; lime, 20 ; iron oxide, 13 per cent. T. Bergman must have confused zirconia with alumina. In 1799, J. B. Trommsdorff tried unsuccessfully to obtain a metal from zirconia. The impure metal itself was isolated from Klaproth's *Zirconerde*, by J. J. Berzelius, in 1824, and he reported the results of numerous investigations on this element between 1824 and 1835.

M. H. Klaproth [4] also established the identity of hyacinth from Espailly (Haute-Loire), and of the mineral *zirconite*, reported by G. F. Schumacher from Fredriksvarn, with zircon or zirconium silicate, $ZrSiO_4$.

The composition of zircon and related minerals is very complex, for they may be associated with small quantities of many other elements—tin, lead, bismuth, aluminium, nickel, cobalt, iron, manganese, uranium, the rare earths, zinc, magnesium, calcium, hafnium, copper, lithium, sodium, potassium, and, maybe, traces of radium, 75–865×10^{-12} grms. per gram, with occluded helium and neon.[5] Accordingly, B. Lindemann proposed to call this group of minerals *polycrasilites*—from πολύς, many ; κρᾶσις, a mixture.

Some of the impurities are retained very persistently by the zirconia precipitated during analysis, and mixtures have been reported as new elements or rather new earths—*e.g.* A. Breithaupt [6] reported the element *ostranium* from the mineral *ostranite*—a decomposition product of zircon ; L. F. Svanberg reported *Norerde* or *noria* to be a new earth from zircon and eudialyte ; the element was called *norium*—from Nore, the ancient name of Norway. In 1869, H. C. Sorby reported *jargonia* to be a new earth from zircon of Ceylon ; A. H. Church also considered that the spectroscope showed a new element as a companion of zirconia, and he named it *nigrum*. The spectrum of certain mixtures of zirconium and uranium oxides does not resemble the joint spectrum of the individual oxides. In 1901, K. A. Hofmann and W. Prandtl reported that about half of the so-called zirconia obtained from euxenite from Brevig really consisted of a similar earth—*Euxenerde* or *euxenia*—supposed to be an oxide of an element with a rather higher atomic weight than zirconium. None of these reports has been confirmed satisfactorily.

§ 2. The Occurrence of Zirconium

Zirconium does not occur free in nature. It is commonly found as silicate, oxide, etc. Zirconium was once considered to be a scarce element, but F. W. Clarke,[1] and F. W. Clarke and H. S. Washington have estimated that it is almost as abundant as carbon, and constitutes nearly 0·017 per cent. of the earth's lithosphere ; and

J. H. L. Vogt estimated 0·01 to 0·02 per cent. ; for comparison, F. W. Clarke, and J. Joly estimate that 27·7 per cent. of that crust is silicon, 0·46 per cent. titanium, and 0·002 per cent. thorium.   This subject has been also discussed by J. F. Kemp, and W. Lindgren.

Although so widely distributed, large workable deposits are rare.   Prior to the discovery of baddeleyite in 1892, zircon was the most important source of zirconium. Both these minerals are discussed elsewhere—baddeleyite with zirconium dioxide, zircon, with the silicates.   In addition to the minerals [2] where zirconium occurs as an essential constituent, there are numerous others where it appears as a secondary constituent, and it is found as an occasional constituent of nearly all minerals.   The oxide may be associated as an acidic radicle with the oxides of titanium, silicon, thorium, cerium, niobium, or tantalum.

The oxide *baddeleyite* has 80 to 98 per cent. ZrO_2.   Complex *zirconates* are represented by *zirkelite*, $(Ca,Fe)O.2(Zr,Ti,Th)O_2$, which has 50 to 53 per cent. zirconia ; *uhligite*, $Ca(Zr,Ti)_2O_5.Al_2TiO_5$, has up to 33 per cent. ZrO_2 ; *hiörtdahl-ite*, $4Ca(Si,Zr)O_3.Na_2ZrO_2F_2$, with 21 to 22 per cent. of ZrO_2 ; *guarinite* is closely related to hiörtdahlite ; *rosenbuschite*, $6CaSiO_3.2Na_2ZrO_2F_2.TiSiO_3.TiO_3$, with 18 to 20 per cent. ZrO_2 ; *wöhlerite*, $12R(Si,Zr)O_3.R(Cb_2O_5)$, with 15 to 23 per cent. ZrO_3 ; *polymigmite*, $5RTiO_3.5RZrO_3.R(Cb,Ta)_2O_6$, with 29 to 30 per cent. ZrO_2 ; and *eudialyte*, and *eucolite*, $Na_{13}(Ca,Fe)_6Cl(Si,Zr)_{20}O_{52}$, with 11 to 17 per cent. of ZrO_2.   The silicate is represented by *zircon*, $ZrSiO_4$, with 61 to 67 per cent. ZrO_2, and its numerous varieties—*e.g.* azorite, beccarite, calyptolite, hyacinth, jargon, and *ostranite*—and altered forms—*e.g.* adelpholite, alvite, anderberjite, auerbachite, cyrto-lite, malacone, œrstedite, oliveiraite, orvillite, and tachyaphaltite.   A silicate *nœgite*, $ZrSiO_4$, is also associated with the rare earths.   More complex silicates are represented by *lävenite*, $R(Si,Zr)O_3.Zr(SiO_3)_2.RTa_2O_6$, with 28 to 32 per cent. ZrO_2 ; *hainite*, $R(Si,Zr)O_3.Zr(SiO_3)_2.RTa_2O_6$, with 28 to 32 per cent. ZrO_2 ; *catapleiite*, $H_4(Na_2,Ca)ZrSi_3O_{11}$, with 30 to 40 per cent. ZrO_2 ; *elpidite*, $H_6Na_2ZrSi_6O_{18}$, with 20 to 21 per cent. ZrO_2.

The tantalum and columbium minerals—*annerödite*, with 1 to 2 per cent. ZrO_2 ; *chalcolamprite*, with 5 to 6 per cent. ZrO_2 ; *columbite*, with 1 to 11 per cent. ZrO_2 ; *fergusonite*, with up to about 2 per cent. ZrO_2 ; *loranskite*, with about 20 per cent. ZrO_2 ; *pyrochlore*, with 0 to 5 per cent. ZrO_2 ; *samarskite*, with 0 to 4 per cent. ZrO_2 ; *sipylite*, with 2 to 3 per cent. ZrO_2.   The thorum minerals *auerlite*, and *thorianite* have from 0 to 3 per cent. ZrO_2.   The titanium mineral *leucosphenite* has up to 5 per cent. ZrO_2 ; and *lorenzenite* up to 12 per cent. ZrO_2.   The scandium mineral *wiikite;* the uranium mineral, *uraninite;* the yttrium mineral *xenotime;* the cerium minerals *cerite* and *monazite*, all may carry up to about 8 per cent. of zirconia.   Similarly, also, with the complex rare earth minerals : *arrhenite* has 3 to 4 per cent. ZrO_2 ; *tritomite* has 1 to 3·6 per cent. ZrO_2 ; *erdmannite* or *michaelsomite* has 2·14 to 5·44 per cent. ZrO_2 ; *euxenite* has up to 2 per cent. ZrO_2 ; *endeolite* has up to 4 per cent. of ZrO_2 ; and *johnstrupite* and *mosandrite* have respectively 2·84 and 7·43 per cent. ZrO_2.   Specimens of *arfvedsonite* or *riebeckite* correspond with a soda-hornblende, $FeSiO_3.2NaFe(SiO_3)_2$, and have up to 7 per cent. of zirconia ; H. S. Washington reported 2·67 per cent. of zirconia in *œgirite*.

Zirconium minerals—chiefly zircon—occur in many deposits—clays, sands, etc. —derived from the weathering of granitic and pegmatitic rocks.   It occurs in the alluvial sands of Ceylon, and Travancore.   According to J. P. Iddings,[3] it occurs in Norwegian syenites, and Canadian limestones.   J. D. Dana reported it in various auriferous sands and gravels ; and H. Rösler, in many clays.   M. Mazade [4] reported zirconium in the mineral waters of Nérac, and also in their ochreous deposits, but O. Henry questioned the accuracy of the analyses.   N. G. Sefström reported zirconium in the furnace slags of Taberg, Sweden.   According to H. A. Rowland,[5] F. W. Dyson, and J. N. Lockyer, zirconium occurs in the sun ; M. Merrill reported zirconium bands in the spectra of stars ; and H. Laspeyres, and E. Cohen, in meteorites.[6]

§ 3. The Extraction of Zirconia from the Minerals

The process employed for extraction of zirconium from the native and impure oxides, or the native silicates, depends on the degree of purity desired. In any case, it is necessary to pulverize the mineral to a fine state of subdivision, and this operation, said M. Weibull,[1] is facilitated by heating and suddenly cooling the mineral. Silica, and iron may not be objectionable, or it may be necessary to remove one or both these constituents. R. C. Gosreau concentrated the zircon of the crushed ore by means of pulsating tables. J. G. Thompson found that 90–95 per cent. of the silica can be removed from zirkite ore by heating a mixture of the ore and carbon in an electric furnace above 2220°. Hot sulphuric or hydrochloric acid, or aqua regia, will remove most of the iron from powdered red baddeleyite without undue loss by dissolution of the zirconia. E. Wedekind recommended sulphuric acid for baddeleyite. J. W. Bain and G. E. Gollop used conc. sulphuric acid for zirkite ore. A. J. Phillips mixed the zirconium with about 4 per cent. of petroleum coke, and heated the briquettes to 900° in a stream of moist chlorine. E. J. Pugh sublimed the zirconium as chloride by heating the ore in a stream of chlorine. G. Siebert and E. Korten, J. W. Bain and G. E. Gollop, A. L. D. d'Adrian, and H. von Siemens and H. Zander opened the raw material by heating it with halogens in the presence of carbon at a high temp. Hot conc. hydrofluoric acid will not remove the silica from zirconium silicate, $ZrSiO_4$. If silica is to be removed, or a high degree of purity is desired, it is necessary to open up the mineral by sintering or fusion, with suitable fluxes. According to K. Rördam, eudialyte can be opened by digestion with twice its weight of hydrochloric acid; two-thirds of the zirconium passes into soln., and the remaining third is removed from the associated silica by digestion with sulphuric acid. E. Linnemann recommended a preliminary treatment of the powdered mineral with hydrochloric acid to remove the iron; or else heating the zircon in the vap. of hydrogen chloride before the fusion with alkali, so as to obtain a porous, easily decomposed mass. In most cases, however, this operation is superfluous. The methods of extractions have been critically examined by E. Linnemann, W. R. Schoeller, R. Lehmann, and J. W. Marden and M. N. Rich.

1. *Fusion with alkali hydroxides or carbonates.*—M. H. Klaproth, and J. J. Berzelius fused the mineral with 4 to 5 parts of its weight of potassium hydroxide.

M. E. Chevreul, and F. Dubois and A. A. de Silveira used 2 parts of potassium hydroxide, and kept the mixture in a fused state for $2\frac{1}{2}$ hrs. in a silver crucible. J. J. Berzelius also used a mixture of potassium carbonate and sodium hydroxide; F. Wöhler, T. Scheerer, R. Hermann, E. C. Rossiter and P. H. Sanders, O. Ruff, L. M. Dennis and A. E. Spencer recommended sodium carbonate; H. L. Wells and F. W. Foote used 4 parts of sodium carbonate to 1 of ore; W. Henneberg, 0·5 part of potassium nitrate to 4 of sodium carbonate; F. Stolba, a mixture of 3 parts of potassium carbonate and 2 of potassium fluoborate; and F. G. Jackson and L. I. Shaw, a mixture of sodium carbonate and borax. P. Berthier also used a mixture of sodium carbonate and sulphur; and J. Gordon a mixture of the alkali hydroxide or carbonate with sodium or calcium chloride. P. Berthier used either sodium hydroxide or carbonate, or a mixture of the two. He said that the soda fluxes are preferable to the potash fluxes because the latter are more inclined to form sparingly soluble double salts. J. W. Bain and G. E. Gollop examined the efficiency of the process. P. Berthier, and D. E. Melliss recommended using 3 parts of sodium hydroxide to 1 of the powdered ore; and E. Linnemann, G. H. Bailey, and F. P. Venable used 10 parts of sodium hydroxide and 1 of sodium fluoride to 1 of ore. H. S. Cooper said that heating the ore to redness and quenching facilitates its decomposition by the fused alkali. F. Stolba decomposed zircon by heating it with a soln. of sodium hydroxide in an autoclave. F. P. Venable thus applied this process :

The zircon is pulverized roughly in an iron mortar, and then ground in an agate mortar until the powder will pass through a 100-mesh sieve ; the powder is boiled repeatedly with strong hydrochloric acid and washed with water. The fusion is conducted in a nickel crucible ; 400 grms. of sodium hydroxide are first fused, then 20 grms. of dry sodium fluoride are added, and when the mass is highly heated, the 100 grms. of zircon are dropped in ; any bubbling over of the mass is prevented by the temporary removal of the flame. When the action ceases, the molten mass is poured on to a sheet of nickel, and as soon as it has solidified it is plunged into water ; the sodium silicate and a negligible amount of the zirconate pass into soln., but the bulk of the latter remains behind, and is dissolved in hydrochloric acid. The soln. is then subjected to repeated evaporation to dryness and treatment with hydrochloric acid, to remove silica and hydrofluoric acid ; the zirconium being ultimately precipitated as hydroxide by means of ammonia. The hydroxide, after thoroughly washing by decantation, is dissolved in the smallest possible quantity of conc. hydrochloric acid, the soln. evaporated to dryness, and the zirconium oxychloride obtained washed in a funnel with a mixture of conc. hydrochloric acid with 4 parts of alcohol ; any zirconium oxychloride passing into soln. can be recovered. The white mass in the funnel is then repeatedly crystallized from strong hydrochloric acid, the zirconium oxychloride being obtained in well-formed crystals of glistening whiteness.

During the fusion with alkali hydroxide or carbonate, the silica, zirconia, and titania are presumably changed respectively to the alkali silicate, zirconate, and titanate ; and the iron is converted to ferric oxide. Some of the zirconia probably forms a double alkali zirconium silicate. The fused mass is cooled, and leached with a little water—say 10 litres per kilogram. Part of the sodium zirconate is hydrolyzed by the water, forming the hydroxide in a finely divided state difficult to filter. The insoluble matter consists of the hydroxides of iron, zirconium, and titanium, and some alkali zirconium silicate. These substances, with the exception of silica, are soluble in acids. The zirconium salts are isolated from the acid soln. If hydrochloric acid is used for dissolving the cake, the oxychloride, $ZrOCl_2.8H_2O$, may be crystallized from conc. hydrochloric acid. R. T. Glazebrook and co-workers gave $Zr_5O_8Cl_4.22H_2O$ for the composition of the product. The oxychloride process was used by J. J. Berzelius, G. H. Bailey, R. Hermann, F. P. Venable and C. Baskerville, M. E. Chevreul, T. Scheerer, N. J. Berlin, E. Linnemann, F. P. Venable, H. Moissan and F. Lengfeld, J. M. Matthews, M. Hanriot, etc. If sulphuric acid be employed for dissolving the cake, the basic sulphate can be crystallized out. Zirconium sulphate has a maximum solubility in a soln. with 61 per cent. of SO_3 ; and, on standing, the acid sulphate, $Zr(SO_4)_2.H_2SO_4.3H_2O$, crystallizes out. If a conc. soln. of the mixed sulphates of iron, titanium, and zirconium be kept boiling for some time, a

basic sulphate is precipitated. Thus, K. Leuchs obtained $4ZrO_2.3SO_3.14H_2O$. R. T. Glazebrook and co-workers added alkali to the cold acid soln. until a permanent white precipitate began to form, and allowed the precipitation to continue without further addition of alkali. In illustration, E. C. Rossiter and P. H. Sanders' process may be cited :

Fifty grams of the powdered ore are fused in an iron crucible with 50 grms. of sodium hydroxide ; the mixture is stirred until frothing ceases, and a granular powder is obtained, the heating being then continued at dull redness for 2 hrs. The mass, while hot, is poured into 1·5 litres of water, the soln. filtered, the insoluble residue treated with hydrochloric acid, and evaporated to dryness. The dry residue is extracted with hot water and the soln. filtered. This soln. is diluted to 1·5 litres, boiled after the addition of a slight excess of sulphurous acid, and normal sulphuric acid is added gradually until the mixture becomes quite thick. After a short time, the whole of the zirconia is precipitated as a basic sulphate ; the precipitate is collected, washed, dried, and ignited to form the oxide, or the precipitate may be suspended in water, treated with alkali, and the hydroxide collected, dried, and ignited.

M. N. Rich allowed the soln. of sulphate to stand some days when the basic sulphate is precipitated. L. W. Ryan precipitated the basic sulphate in a granular form by adding sodium chloride and sodium carbonate or hydroxide to the soln. of the sulphate. The basic sulphate process was used by S. R. Paykull, C. M. Warren, R. Ruer, O. Hauser, etc. The basic sulphate can be converted into the oxide by ignition, or into the hydroxide by suspending it in water and agitating with ammonia. P. Askenasy, and B. Havas heated the acid soln., containing not more than 9 per cent. zirconium hydroxide, in an autoclave at, say, 200°. The zirconium hydroxide was precipitated in a form which is easily filtered. W. R. Loveman patented a process in which it was claimed that the treatment of the fused cold cake with water removed the silica from the cake obtained by melting the powdered ore with 8 times its weight of sodium carbonate. The residue, digested with hydrochloric acid (1 : 1), left a hydrated zirconium oxide which, after ignition, contained 99·55 per cent. of zirconium oxide; 0·10 per cent. Fe_2O_3; 0·2 per cent. TiO_2; and 0·15 per cent. silica.

2. *Fusion with alkaline earths, or lead oxide.*—R. Bayer heated a mixture of the powdered mineral with $2\frac{1}{2}$ times its weight of barium carbonate at about 1400°, for $2\frac{1}{2}$ hrs. in a graphite crucible. The barium zirconate is extracted from the cold mass with hydrochloric acid, and the acid liquid is evaporated to dryness to make the silica insoluble. The residue is leached with hydrochloric acid, and, on conc., crystals of barium chloride first separate, and finally zirconium oxychloride, $ZrOCl_2.8H_2O$. This process is quite good for removing the silica, but not the iron. P. Berthier opened up the mineral by melting it with about $2\frac{1}{2}$ times its weight of lead oxide ; or by heating it with 0·3 times its weight of powdered quartz, and 1·1 times its weight of calcium carbonate, in a carbon crucible. In the latter case, the iron is reduced, and collects at the bottom of the crucible. J. Gordon used calcium oxide mixed with sodium or calcium chloride.

3. *Fusion with alkali pyrosulphate, or hydrosulphate.*—B. Franz, N. J. Berlin, A. Stromeyer, L. E. Barton and C. J. Kinzie, R. Hermann, R. Lehmann, and J. M. Matthews fused the mineral with potassium hydrosulphate. Alkali pyrosulphate, or nitre-cake can also be used. About 20 parts of the alkali sulphate to 1 of ore are used ; if the proportion is less than 10 : 1, the decomposition may be incomplete. A graphite, fused silica, or cast-iron crucible can be used. The cold cake can be heated with conc. sulphuric acid till all is dissolved ; and when cold, poured into cold water. The clear soln. is decanted or filtered from the silica which separates, and is then ready for the recovery of the zirconium. In the alternative process, the cold cake can be digested with hot water and the soln. filtered from the silica, etc. The filtrate contains the zirconium sulphate or oxysulphate, with some silica, iron, alumina, and sodium sulphate. This can be treated by the basic sulphate process—*vide supra*. J. H. de Boer fused the ore with potassium hydrosulphate, extracted the fused mass with water, precipitated the metals as hydroxides, and

redissolved the precipitate in conc. hydrochloric acid. From the strongly acid soln. zirconium is precipitated as the phosphate, $Zr(HPO_4)_2$, and is thereby separated from all other metals except hafnium. The phosphate is readily washed by decantation with hydrochloric acid and water, and may then be dissolved in hydrofluoric acid and the zirconium reprecipitated as hydroxide.

4. *Fusion with alkali hydrofluoride.*—J. C. G. de Marignac recommended fusing the mineral with 2 to 3 times its weight of potassium hydrofluoride : ZrO_2+4KHF_2 $=K_2ZrF_6+2H_2O+2KF$. The cold cake is boiled with water containing hydrofluoric acid, and the insoluble alkali fluosilicate filtered off. On cooling the hot soln., crystals of alkali fluozirconate are deposited, and this salt can be recrystallized from water. The fluozirconate can be treated with sulphuric acid and evaporated to dryness, and the potassium sulphate removed by lixiviation with water ; or, as recommended by R. Hornberger, the evaporation with sulphuric acid can be carried to a point where the hydrofluoric acid and most of the sulphuric acid are driven off, and the aq. soln. heated with ammonia as indicated below. This process, or a simple modification of it, was used by B. Franz, G. H. Bailey, H. Traube, H. Rose, J. W. Bain and G. E. Gollop, R. Lehmann, and J. Potyka. J. Körner fused the ore with sodium fluosilicate to get a product soluble in sulphuric acid.

5. *Heating the ore mixed with carbon, or calcium carbide, or oxide in a high-temperature electric furnace.*—L. Troost heated a mixture of calcium oxide, zircon, and carbon in an electric arc-furnace for a few minutes. The reaction is represented : ZrO_2 $+4C=ZrC_2+2CO$. All but about 1 to 1·5 per cent. of the silica was volatilized and also most of the iron oxide, and other impurities. The product was extracted with water and dil. hydrochloric acid ; and the residue was treated with chlorine at 300° so as to furnish zirconium chloride. There is a small loss of zirconia by volatilization at the high temp. employed. This process recalls F. Wöhler's process in which chlorine gas was passed over an intimate mixture of the ore and carbon heated in a porcelain or hard glass tube. He said, " The silicon chloride is volatilized and the zirconium chloride sublimed in such a state as to be completely soluble in hydrochloric acid." L. Troost, L. Burgess, and H. Moissan and F. Lengfeld prepared a crude zirconium carbide by heating a mixture of the mineral and carbon in the electric arc furnace. The carbide was heated in chlorine, and the resulting chloride dissolved in hydrochloric acid. E. Wedekind dissolved the zirconium in aqua regia and precipitated zirconium hydroxide with aq. ammonia. Crystalline zirconium oxychloride separates from the cooling soln. L. Renaux, and E. Wedekind said that in this process calcium carbide gives better results than carbon alone. The main reaction is represented : $ZrSiO_4+2CaC_2=ZrC+SiC+2CaO+2CO$. Modifications of the process have been patented by L. E. Barton, O. Hutchins, C. J. Kinzie, H. Herzfeld, T. R. Haglund, L. Burgess, and P. Jost and P. Plocker.

The zirconium hydroxide precipitated by ammonia from soln. of zirconium salts is contaminated with hydroxides of other elements which may be present, and which are likewise precipitated by this agent—*e.g.* iron, titanium, chromium, aluminium, vanadium, and the rare earths. The iron, titanium, and aluminium are the most difficult to separate from zirconium. Zirconium can be separated from iron by the use of the double fluorides; by the oxychloride process ; basic and acid sulphate ; hydrolytic dissociation ; and the phosphate process. The last was recommended by J. H. de Boer. For the separation of hafnium, *vide infra.* In addition to the processes of separation just described, a number of others have been recommended mainly for purposes other than commercial.

(1) F. Dubois and A. A. de Silveira, and F. Wöhler boiled the precipitate obtained by adding ammonia, with a soln. of oxalic acid, and separated the soluble ferric oxalate from the insoluble zirconium oxalate by filtration and washing. The zirconium oxalate was converted to oxide by ignition, or dissolved in acid, and the hydroxide precipitated by aq. ammonia. N. J. Berlin found that if too much oxalic acid is used some zirconium oxalate is dissolved. (2) M. H. Klaproth, J. L. W. Gruner, J. J. Berzelius, T. Scheerer, G. Possetto, H. Geisow, and P. Horkheimer treated the mixed precipitate with alkali or ammonium hydroxide. (3) E. Linnemann, F. P. Venable, and J. M. Matthews separated ferric chloride

from zirconium chloride by extracting the mixed soln. with ether, the ferric chloride follows the ether. (4) F. S. Havens and A. F. Way, by exposing the mixed oxides at a temp. of 200° to a stream of hydrogen chloride and chlorine—the ferric chloride alone is volatilized. (5) E. T. Allen, by the addition of phenylhydrazine, when the zirconium and aluminium salts are precipitated. (6) H. Geisow, P. Horkheimer, E. Wedekind, F. Wöhler, L. M. Dennis and A. E. Spencer, R. Hermann, C. Baskerville, and P. Berthier, by treating the neutral soln. with sulphur dioxide, when basic zirconium sulphate is precipitated. (7) J. J. Berzelius, R. Hornberger, H. Geisow, P. Horkheimer, E. Wedekind, O. Hauser, C. F. Rammelsberg, C. F. Chandler, W. C. Brögger, and G. von Knorre, by adding ammonium sulphide to the alkaline soln. of the two chlorides in the presence of alkali tartrate, when ferric sulphide is alone precipitated. (8) M. F. Chancel, W. R. Loveman, R. Hermann, and A. Stromeyer, by boiling the slightly acid soln. with sodium thiosulphate, when zirconium is precipitated. (9) G. H. Bailey, F. P. Venable, O. Hauser, R. Ruer, H. Geisow, and P. Horkheimer, by the action of conc. hydrogen dioxide on a feebly acid soln. of zirconium sulphate, when hydrated zirconium peroxide is precipitated—iron, aluminium, and titanium remain in soln. In alkaline soln., the iron is precipitated and the zirconium salt remains in soln. (10) G. von Knorre, and E. A. Atkinson and E. F. Smith separated the iron and zirconium by treatment of the liquid, acidified with tartaric acid, with a soln. of nitro-β-naphthol, iron is alone precipitated; and (11) L. E. Rivot, K. Daniel and co-workers, and A. Gutbier and co-workers, by heating the mixed oxides in a stream of hydrogen, when the iron is reduced to the metal, which is alone soluble in acids. (12) M. H. Klaproth used an alkali succinate as precipitant for the iron; and (13) C. R. Böhm, sodium nitrate as precipitant for the zirconium. (14) E. W. Washburn and E. E. Libman said that all but a trace of the iron can be removed by heating zirconium oxide to 300° in a stream of carbonyl chloride—*vide* carbonyl chloride. For separating titanium and zirconium, (15) G. Streit and B. Franz acidified the mixed soln. with dil. acetic and sulphuric acids, and, on boiling, the titanium oxide alone was precipitated; (16) F. Pisani reduced the titanium dioxide to the sesquioxide in acid soln. by means of zinc, and on the addition of potassium sulphate, zirconium potassium sulphate was precipitated; and (17) L. Fernandes used thallous sulphate as an auxiliary agent in separating zirconium and thorium from the rare earths. (18) According to W. F. Hillebrand, R. J. Carney, P. Hautefeuille and J. Margottet, and A. Knop, when hydrogen dioxide is added to a soln. containing sodium phosphate, a basic zirconium phosphate is precipitated; and, according to J. T. Davis, (19) by warming the faintly acid soln. with sodium iodate, zirconium iodate is precipitated—thorium iodate is insoluble in oxalic acid, but zirconium iodate is soluble.

§ 4. The Preparation of Zirconium

The isolation of zirconium of a high degree of purity is not easy. J. B. Tromms-dorff's [1] and H. Davy's attempts were not successful. The chief difficulties are connected with the resistance offered by the oxide to reduction, the tendency of the metal to oxidation, the high m.p. of the metal, and the ease with which the reduced metal unites with other substances. According to G. H. Bailey, zirconia is not reduced by hydrogen ; and, according to L. Weiss and E. Neumann, it is not reduced by the alkali metals. The metal can be obtained by reducing the halogen salts with the alkali metals, and by reducing the oxide with aluminium, magnesium, calcium, or carbon. The product, however, is usually impure because the metal so readily combines with the reducing agent, and with hydrogen, carbon, oxygen, and even nitrogen gas. In consequence, the early reports of the preparation and properties of this element refer not to the metal, but rather to the metal contaminated with from 5 to 10 per cent. of impurity—carbide, silicide, nitride, hydride, or oxide. The so-called crystalline zirconium of the nineteenth century was probably an alloy of the metal with aluminium. In illustration, six samples of zirconium, prepared by the early methods, were found by E. Wedekind and S. J. Lewis to contain from 24·98 to 92·64 per cent. of free zirconium ; 2·55 to 53·68 per cent. of zirconium in the form of oxide ; and 1·24 to 8·70 per cent. of zirconium in the form of nitride.

L. Troost claimed to have made *graphitic zirconium* by reducing sodium zirconate by iron at a red heat, but this has not been confirmed since iron does not reduce zirconia under these conditions. J. W. Marden and M. N. Rich tried zinc, lead, silver, and manganese as reducing agents for potassium fluozirconate or zirconia, but the results were inferior to those obtained with aluminium as a reducing agent. H. N. Warren reported that when a rod of magnesium is wrapped in coils of asbestos

paper, and dipped into a soln. of a zirconium salt, zirconium metal is obtained. The report has not been confirmed.

E. Sander patented a method of making zirconium by heating the nitride or hydride under reduced press., pumping off the gases as they are formed. Other methods proposed for making zirconium are as follow :

(1) *The reduction of halides by the alkali metals.*—In J. J. Berzelius' process, a mixture of dry potassium fluozirconate and potassium was heated over a spirit-lamp in an iron tube—6 mm. diameter and 30 mm. long—closed at one end. The reduction proceeded quietly, and the mass was stirred frequently with an iron wire. The cold mass was washed successively with dil. hydrochloric acid ; and a soln. of ammonium chloride ; and finally with alcohol. L. M. Dennis and A. E. Spencer used a somewhat similar process. L. Weiss and E. Neumann found that the amorphous or colloidal product so obtained contained about 93·7 per cent. of zirconium. The chief impurity is zirconium oxide which is formed by the action of water or soda-lye during the washing. A 98 per cent. metal was obtained by treating the product first with absolute alcohol in place of water, and then washing with dil. acid, etc. E. Wedekind filled a copper tube under ether, with the mixture of potassium and potassium zirconium fluoride, and then pumped the air from the tube. The mixture was dried at 200° in vacuo, and then heated to 300°. The product contained 71 per cent. of free zirconium, and 16·6 per cent. of combined zirconium. The product was pyrophoric, and fired when exposed to the air 14 hrs. after cooling. Like J. J. Berzelius, subsequent workers have found that the best results are obtained when potassium fluozirconate is used as the source of zirconium. E. Wedekind, and L. Weiss and E. Naumann found sodium gave better results than potassium. L. Troost reduced zirconium tetrachloride by passing its vap. over hot sodium, or an alloy of zinc and sodium in a porcelain tube. D. Lely and L. Hamburger reduced the tetrachloride by sodium in a bomb. The metal was obtained in plates which could be pressed into rods. E. Podszus heated potassium fluozirconate and sodium in a steel bomb fitted with a molten lead seal. The closed bomb was revolved for about 40 hrs. at 200° to produce intimate admixture. A few minutes' heating started the reaction, and sodium vap. passed through the lead seal. The resulting finely crystalline metal contained 99·3 per cent. zirconium. M. A. Hunter and A. Jones, and H. S. Cooper reduced zirconium chloride by a similar process and obtained the granular metal of 96 per cent. purity. J. W. Marden and M. N. Rich have reported on this process.

(2) *The reduction of the oxide by calcium.*—A. Burger obtained 98·7 per cent. zirconium and 0·18 calcium by heating a mixture of zirconia and an excess of calcium. The reaction is $2ZrO_2+2Ca=CaZrO_3+Zr+CaO$; and at a higher temp., near 1050°, $CaZrO_3+2Ca=Zr+3CaO$. E. Wedekind, and H. Kuzel and E. Wedekind obtained very fair specimens of zirconium by heating an intimate mixture of zirconia with an excess of fine calcium shavings in an iron tube closed at one end, and under a reduced press., —0·1·to 0·5 mm. The heating was discontinued as soon as the reaction commenced. The cold product was powdered and washed successively with cold water ; acetic acid ; dil. hydrochloric acid ; and then with water, until the washings showed the absence of calcium chloride. After a final washing with acetone, the product was dried—first at ordinary temp. ; then in vacuo at from 250° to 300° ; and finally in an evacuated porcelain tube between 800° to 1000°. The resulting metal contained 99·09 per cent. of zirconium ; and the yield was 97·5 per cent. of the theoretical. An attempt to purify the product further by again heating it in a metal tube with calcium gave a less pure product. O. Ruff and H. Brintzinger obtained 97 per cent. zirconium by reducing the oxide with a sodium-calcium alloy.

(3) *The reduction of the oxide or halide by magnesium.*—According to T. L. Phipson and G. H. Bailey, zirconia is reduced by molten magnesium. C. Winkler passed hydrogen over a heated mixture of zirconia and magnesium, and obtained a mixture of zirconium hydride and unchanged zirconia. The unchanged zirconia is sup-

posed by some to be really a suboxide (*q.v.*). L. M. Dennis and A. E. Spencer obtained a product with 80·7 per cent. of zirconium, and 18·0 per cent. of oxygen. According to L. Troost, and W. R. Whitney, amorphous zirconium can be prepared by passing the vap. of zirconium tetrachloride over red-hot magnesium. E. Wedekind heated thin pencils of alkali fluozirconate with magnesium in an electric furnace, and obtained 96·55 per cent. zirconium and 4·14 per cent. oxygen. He also heated zirconia and 40 per cent. excess magnesium in a nickel crucible and obtained a colloidal form of zirconium. R. Escales patented a process for the preparation of zirconium involving the use of the rare-earth metals, or mixtures of their alloys with magnesium or aluminium.

(4) *The reduction of the halide or oxide by aluminium, etc.*—L. Troost passed the vapour of zirconium tetrachloride over heated aluminium and obtained a spongy mass. The surface layers had a crystalline structure. He also heated a mixture of sodium or potassium fluozirconate, R_2ZrF_6, with one and a half times its weight of aluminium in a crucible to the m.p. of iron, and treated the cold mass with hydrochloric acid (1 : 2) in order to isolate the metal. The product had a crystalline structure. B. Franz said that the fluozirconate, $3KF.ZrF_4$, gives better results than the normal fluozirconate. He used a graphite crucible, and obtained a metal with 1·03 per cent. aluminium, and 0·17 per cent. silicon. S. A. Tucker and H. R. Moody, and E. Wedekind found that the thermite process of H. Goldschmidt and C. Vautin gave a mixture of zirconium with unreduced zirconia and alumina which cannot be readily separated from the metal. L. Weiss and E. Neumann say that there is not enough difference between the heats of formation of zirconia and alumina to give good results by the thermite process involving the reaction : $3ZrO_2+4Al=2Al_2O_3+3Zr+253$ cals. K. A. Kühne patented a thermite process involving reaction : $ZrO_2+2Al+BaO_2=Al_2O_3+BaO+Zr$. J. W. Marden and M. N. Rich did not get good results by this process with zirconia, or potassium fluozirconate. J. W. Marden and M. N. Rich fused a mixture of a silicate ore of zirconium, sodium fluoride, and aluminium in the electric vacuum furnace, and obtained impure zirconium. E. Wedekind tried reducing potassium fluozirconate with aluminium in an electric furnace and obtained an alloy of zirconium with 34 per cent. of aluminium, which could not be removed by acids or alkalies. By melting the product in an electric furnace part, but not all, the aluminium was removed. L. Weiss and E. Neumann purified the zirconium obtained by J. J. Berzelius's process, or the aluminium reduction process, by squeezing the product into rods or pencils and following the method described in connection with titanium, **7**. 41, 4, Fig. 1. The process was investigated by J. W. Marden and M. N. Rich. When the experiment was made with the zirconium-aluminium alloy, in an atm. of nitrogen, at about 10 or 11 mm. press., the aluminium volatilized, and the globules had 99·76 to 99·89 per cent. zirconium. This was considered to be the purest zirconium ever made. H. Fischvoigt and F. Koref, and A. E. van Arkel and J. H. de Boer made zirconium by passing the vapour of the tetraiodide over a heated tungsten filament—*vide* titanium.

(5) *The reduction of zirconia by hydrogen, calcium carbide, carbon, boron, or silicon.*—L. Troost tried to eliminate silicon from zirconia by compressing intimate mixtures of zirconia and carbon into small cylinders and heating them in the electric arc furnaces in an atm. of carbon dioxide—the residual zirconium carbide contained up to 1·5 per cent. of silica. L. Renaux modified the process by using calcium carbide. The reaction, according to E. Wedekind, is : $ZrSiO_4+2CaC_2=ZrC+SiC+2CaO+2CO$, and it is possible by this process to volatilize the silicon carbide almost completely. In the attempt to reduce a similar mixture of zirconia and sugar-charcoal contained in a vessel lined with zirconia, heated in an arc-furnace, L. Troost, and H. Moissan obtained zirconium containing 4 to 5 per cent. of carbon which was present presumably as carbide. H. C. Greenwood, and J. N. Pring found that the reduction of zirconia by carbon begins about 1400°. H. Moissan stated that when zircon is heated in a carbon crucible in the electric arc-furnace, he obtained

a metal containing about 5 per cent. of carbon, and no nitrogen ; the silica passed off as white fumes. He obtained zirconium from this carbide by fusing it in the presence of an excess of fused zirconia, and said that the metal is free from carbon and nitrogen, but still contains some oxide. His description of zirconium shows that he was probably mistaken as to the purity of his preparation. He reduced zirconia with carbon, either together or admixed with lime, in an electric arc-furnace, and obtained zirconium carbide which he claimed is reduced to the metal when the zirconia is present in excess. L. Burgess modified the process a little. According to E. Wedekind, when a mixture of zirconia and boron is heated in the electric furnace, an impure metal containing boride and carbide is formed ; and with silicon as reducing agent, zirconium silicide is present. H. von Wartenburg and co-workers reduced zirconia by heating it in an atm. of hydrogen at 5 atm. press., and 2500°, provided a metal like tungsten is present to dissolve the zirconium.

(6) *The electrolytic reduction of zirconium salts.*—A. C. Becquerel electrolyzed a soln. of zirconium tetrachloride mixed with a small proportion of ferric chloride contained in the cathode compartment. The platinum wire cathode in 24 hrs. was covered with a steel-grey film of crystals of zirconium. The metal readily oxidized on exposure to air. According to L. Troost, the electrolysis of molten potassium fluozirconate, or sodium chlorozirconate, furnishes crystalline zirconium, but E. Wedekind was able to obtain only an impure powder, greyish-black in colour, and easily oxidized. J. W. Marden and M. N. Rich could obtain only the impure amorphous metal by L. Troost's process.

J. J. Berzelius mentioned that in washing out the soluble matters from the product of the action of potassium on the alkali fluozirconate, a soln. of ammonium chloride in hydrochloric acid should be used because, with water alone, the whole of the zirconium is carried in a state of minute division, through the pores of the filter. The soln. of ammonium chloride or other saline substances thus flocculate the **colloidal zirconium** into large flakes. The suspended zirconium is also flocculated by heat. C. Winkler obtained similar results in the reduction of zirconium dioxide or tetrachloride with magnesium. E. Wedekind, H. Kuzel, and W. R. Whitney obtained analogous results.

§ 5. The Physical Properties of Zirconium

Zirconium was formerly stated to exist in three forms : crystalline, graphitic, and amorphous. The variety formerly called **crystalline zirconium,** prepared by L. Troost,[1] was shown by E. Wedekind, and L. Weiss and E. Neumann to be really an alloy of aluminium and zirconium (*q.v.*), and it is necessary to distinguish between crystalline zirconium, an aluminium alloy ; crystalline zirconium in the ordinary sense of the term ; and the **graphitic zirconium** reported by L. Troost—*vide supra.* There are really only two forms now recognized, the crystalline metal and the amorphous. The 99 per cent. metal which has been heated in the electric furnace is crystalline, and the fractured surface is white, resembling cast iron. The brassy yellow of the metal is due to a surface film of nitride. The coherent metal, said J. W. Marden and M. N. Rich, has a white **colour,** a metallic lustre, and takes a fine polish like nickel. E. Wedekind obtained **amorphous zirconium** as a bluish-black powder when potassium fluozirconate or other halogen salt is reduced by magnesium or an alkali metal. The black powder resembles carbon, and is thought to be a colloid. When this powder is washed with a dil. acid, it forms a colloidal soln. which is dark blue by transmitted light. The soln. is coagulated by the addition of hydrogen dioxide, by salts with an alkaline reaction, and by warming. The gel retains water very pertinaciously so that it must be heated in vacuo to at least 200°, in order to eliminate the water. After heating to about 300° in vacuo, the amorphous zirconium is pyrophoric when exposed to the air. E. Wedekind said that it has not yet been clearly proved if the so-called colloidal zirconium is a zirconium hydride or nitride, or the amorphous form of the metal. The probability is in favour of the latter suggestion ; and that the so-called amorphous zirconium is the crystalline metal in a very finely divided state. A. W. Hull found that the **X-radiogram** of zirconium corresponds with the hexagonal system and the axial ratio $a : c = 1 : 1.59$. The space-lattice shows the atoms have a slightly distorted form of the close-packed hexagonal arrangement. The side of the unit triangular prism is 3·23 A., and the height, 5·14 A. The X-radiogram was also examined by A. E. van Arkel and J. H. de Boer. J. Königsberger said that the zirconium prepared by electrolysis crystallized in the cubic system.

The properties of zirconium reported by different workers are sometimes confused, and not always concordant. The reason will be obvious from what has been said on the purity of the metal. L. Troost gave 4·15 for the **specific gravity** of zirconium, probably contaminated with the aluminide ; S. Meyer, 4·08 ; and H. Moissan, 4·25, for a sample probably contaminated with carbide. E. Wedekind gave for the sp. gr. of the metal with 99·55 per cent. zirconium, and 4·14 per cent. of oxygen ; and L. Weiss and E. Neumann gave 6·4 for 99·8 per cent. zirconium. Accepting 6·4 as the best representative value, the **atomic volume** is 14·16. R. Gross, and E. Donath and J. Mayrhofer compared the properties of elements with respect to their at. vol. J. J. van Laar calculated b_0 of J. D. van der Waals' equation as 0·00235 ; and for the valency attraction A, $\sqrt{A} = 37$. The **hardness** of the specimen prepared by H. Moissan was said to be 4·7, and he added that the metal will scratch glass and rubies. This, however, refers to a mixture of zirconium and its carbide. J. W. Marden and M. N. Rich add that pure samples of the coherent metal are softer than the impure metal. The sclerescopic hardness is 40 to 45. The metal is quite brittle, and can easily be broken by lightly pounding with a small hammer. The metal is still hard but less brittle at a red heat. L. Weiss and E. Neumann's 99 per cent. zirconium was hard enough to scratch quartz, but not topaz, so that its hardness was between 6 and 7. A. E. van Arkel and

J. H. de Boer found that the metal is soft and ductile like copper, and that it can be easily hammered out, drawn into wire, or rolled into sheet.

There are surprising differences in the reported values for the **melting point** of zirconium. E. Wedekind and H. Kuzel said that the amorphous metal prepared by the calcium reduction process sinters at 1000°; unless the metal softens below its m.p., this low number shows that the metal was impure. L. Troost said that the metal is less fusible than silicon. E. Wedekind reported that the metal of a high degree of purity has a m.p. between 1523° and 1533°—mean 1530°; W. von Bolton gave 2330° and 2380°—mean 2350°; W. R. Mott, 1500°; J. W. Marden and M. N. Rich, 1700°; H. S. Cooper, near 2800°; and W. Guertler and M. Pirani adopted 1700° as the best representative value for the m.p. J. W. Marden and M. N. Rich found that the metal could be sintered at 1600° when air is excluded. No signs of the volatilization of zirconium was observed at 3000°, but W. R. Mott calculated the **boiling point** to be 2900°. J. J. van Laar estimated the **critical temperature** to be 3920°, and the **critical pressure,** 760 atm. W. G. Mixter and E. S. Dana found the **specific heat** of zirconium between 0° and 99·7° to be 0·0660, but the specimen was contaminated with silicon; E. Wedekind and S. J. Lewis gave 0·06725; and E. Wedekind obtained a range from 0·0656 to 0·0735. L. Weiss and E. Neumann found for the highly purified sample, 0·0804, which makes the **atomic heat** unusually high, *viz.* 7·31. All these determinations were made between 0° and about 100°. J. Dewar gave 0·0262 for the sp. ht. and 2·38 for the at. ht. of zirconium between −253° and −196°. G. N. Lewis and co-workers gave 9·5 for the **entropy** of zirconium at 25°. According to J. W. Marden and M. N. Rich, the **thermal conductivity** of amorphous zirconium is very low, and that of crystalline zirconium high. The **heat of combustion** found by L. Weiss and E. Neumann is 1958·7 cals. per gram; 177·5 Cals. per gram-atom; or 44·7 Cals. per gram-eq.

J. H. Gladstone gave 0·242 for the **specific refraction** of zirconium, and 21·9 for the at. refraction. R. Thalén [2] first obtained the **spark spectrum** of zirconium. There are brilliant lines in the green, blue, violet, and in the ultra-violet. Further studies were made by L. Troost and P. Hautefeuille, R. Capron, E. Linnemann, H. A. Rowland, E. Demarçay, O. Lohse, A. de Gramont, F. Exner and E. Haschek, A. Hagenbach and H. Konen, A. G. G. Leonard, and J. M. Eder and E. Valenta. The results show that the most intense lines in the spark spectrum have the wavelengths 3392·20, 3438·39, 3496·40, 3556·89, 3698·41, 3751·85, 3836·98, 3958·39, 3991·31, 3999·18, 4149·43, 4209·21, 4380·12, 4443·31, 4494·78, 4497·27. The most persistent lines—A. de Gramont's *les raies ultimes*—with soln. of different normality N are:

N	0·01	0·001	0·00005	0·00001	0·000005
3698·16	+	?	.	.	.
3572·47	+	+	?	.	.
3505·66	+	+	+	.	.
3496·20	+	+	+	+	.
3438·23	+	+	+	?	.
3391·98	+	+	+	+	+
3273·04	+	+	.	.	.

Where the plus symbol indicates that the line is visible.

The **arc spectrum** was investigated by H. A. Rowland and C. N. Harrison, F. Exner and E. Haschek, W. Vahle, M. A. Catalan, J. M. Eder and E. Valenta, and A. Bachem. The most intense lines have the wave-lengths 3392·14, 3496·38, 3809·49, 3891·53, 3929·71, 3973·63, 4081·40, 4227·94, 4239·49, 4282·32, 4507·32, 4535·90, 4575·69, 4634·30, 4687·99, 4688·63, 4710·23, 4739·68, 4772·50, 4815·80, 6127·64. The effect of *pressure* on the spectral lines was studied by W. J. Humphreys; and the effect of a *magnetic field*—the **Zeeman effect**—by B. E. Moore, and E. F. du Bois. W. Huggins observed that in the oxy-hydrogen flame, zirconia gave a continuous spectrum. J. C. McLennan and A. C. Lewis examined the **ultra-violet spectrum.**

There is no **absorption spectrum** for the colourless zirconium salts.   E. Linnemann showed that J. L. Soret's report of the absorption spectrum of zirconium salts was due to his using impure soln.   If tincture of alkanna be added to a soln. of zirconium chloride, the violet soln. obtained has a red fluorescence, and it has an absorption spectrum with bands between 6030 and 6016 ; 5581 and 5570 ; and 5195 and 5186. With a soln. of the nitrate, the bands lie between 6058 and 6030 ; 5603 and 5581 ; and 5213 and 5195.   In each case, however, the exact location of the bands depends on the conc. of the soln.   For the solar spectrum, *vide* the occurrence of zirconium. The high frequency or **X-ray spectrum** was studied by H. G. J. Moseley, and E. Friman.   B. Walter, B. B. Ray, A. Leide, F. C. Blake and W. Duane, and M. Siegbahn gave in Angström or 10^{-8} cm. units, for the K-series, $a_2a'=0.793$; $a_1a=0.788$; and $\beta_1\beta=0.705$.   D. Coster, E. Hjalmar, and M. Siegbahn gave for the L-series, $a_1a=6.0559$; $a_3a''=6.0272$; and $\beta_1\beta=5.8228$.   R. Berthold studied the relation between the photographic and ionizing effects of X-ray radiation from zirconium.

According to A. Gockel,[3] some samples of zirconium are **radioactive** owing, presumably, to the presence of thorium as impurity.   A. von Antropoff's alleged production of argon from zirconium by the action of **radium rays** has not been confirmed ; nor has W. Ramsay's alleged degradation of zirconium into carbon by the action of radium emanation on zirconium nitrate.

The **electrical conductivity** of amorphous zirconium is low, but that of coherent crystalline zirconium is fairly good; but J. W. Marden[4] said that its conductivity is less than that of iron.   While compressed amorphous zirconium is a non-conductor at low voltages, it becomes a conductor after heating to 1000° in vacuo. The *Nernst lamp* is based upon the use of an electrolytic conductor as a luminous filament, that is to say, of a conductor of which the electric resistance diminishes when the temp. increases.   The filaments of the lamp are formed of oxides of zirconium, thorium, and other rare earth-metals, which become conductors only at a temp. of 600°.   The lamp, therefore, comprises, in the first place, an arrangement that permits of heating the filament to redness before passing a current through it and utilizing it as a luminous body.   For this purpose, a heating coil of wire surrounds the filament.   The coil is traversed first by the current, and after the filament has become incandescent, an interrupter operates automatically and cuts the current off from the heating apparatus.   When the intensity of the current increases in the filament, the difference of potential at the terminals of the filament increases in the first place, remains constant for a short time, and afterward continues to diminish.   The best conditions of operation are those in which the difference of potential is constant.   Increases of a potential would have the great drawback of increasing the intensity of the current in the filament, and consequently of deteriorating it.   In order to prevent this, a special resistance which offers an obstacle to variations in potential is mounted in series with the filament.   The resistance is formed of a very fine iron wire placed in a bulb of hydrogen.   Iron is the one metal whose resistance increases most with the temp.   The result is that it is easily capable of compensating for the inverse variation of the electric conductivity of the Nernst filament.   According to J. Königsberger and K. Schilling, the conductivity of an impure sample of zirconium is nearly the same as that of brass, and is greater than that of carbon, silicon, or titanium, and the resistance, R,

FIG. 1.—Electrical Resistance of Zirconium.

shows a minimum value at about $-100°$, Fig. 1. P. Clausing found the ratio R/R_0 decreases uniformly with temp., when the sp. resistance, R_0, at 0° is 1.64×10^{-4} ohm to 1.81×10^{-4} ohm.   C. R. Böhm measured the conductivity of zirconium filaments.   P. W. Bridgman found the press. coeff. of the resistance is very small, being near -0.0_6398 at 0° and -0.0_6396 at 95°.   Zirconium lies

between palladium and silver in the **electrochemical series** : . . . Au, Pt, Pd, Ta, Zr, Ag, Hg, Cu, . . . when the metal is used as anode, with a platinum wire as cathode. In dil. hydrochloric acid, zirconium becomes coated with a film of oxide, and it then appears to be passive for the current rapidly diminishes. For example, the current of a Zr : Pt-cell fell from 0·4 amp. to 0·2 amp. in 24 mins. Amorphous zirconium is paramagnetic ; L. Troost's aluminium-zirconium alloy was diamagnetic. S. Meyer gave for the **atomic magnetism** $-0·014 \times 10^{-6}$ at 17°. M. Owen examined the thermomagnetic properties of, presumably, the zirconium-aluminium alloy at different temp. K. Honda gave $-0·45 \times 10^{-6}$ for the **magnetic susceptibility** at 18°, and $-0·3 \times 10^{-6}$ at 1150°.

§ 6. The Chemical Properties of Zirconium

Le zirconium a plus d'analogie avec le silicum qu'avec aucun autre élément.—H. Moissan.

Zirconium adsorbs gases very tenaciously, and, according to E. Wedekind and H. Kuzel,[1] if it is to be completely deprived of these gases, it must be heated in vacuo to about 1000°. J. J. Berzelius found that amorphous zirconium can be heated to the softening temp. of glass, in vacuo or in an atm. of hydrogen, without change ; but he added that if zirconium hydroxide be present, the metal became incandescent, and it oxidized by the water from the decomposing hydroxide. E. Wedekind and S. J. Lewis, however, found that when heated below about 700°, zirconium unites with hydrogen, forming the hydride. Carbon and silicon have a marked tendency to form hydrides, but the related elements titanium, zirconium, cerium, etc., do not exhibit the same tendency to unite with **hydrogen.** According to C. Winkler, when zirconia is reduced with magnesium in a stream of hydrogen, and the product treated with hydrochloric acid, a gas is evolved which gives a precipitate with silver nitrate, and is possibly a *gasförmigen Zirkoniumwasserstoff.* This, however, is doubtful. E. Wedekind used boron in place of magnesium as the reducing agent, and when the product was treated with acid, the hydrogen which was evolved burned with a non-luminious flame without smoke, and deposited nothing when passed through a hot tube, and gave no indications of a volatile zirconium hydride. R. Schwarz and H. Deisler obtained indications of C. Winkler's gaseous hydride, but R. Schwarz and E. Konrad could not find any signs of zirconium in the deposits obtained by passing the gas through heated glass tubes. The deposits consisted mainly of silicon from the silicon hydride ; some phosphorus and sulphur hydrides are also evolved. J. W. Marden and M. N. Rich state that when zirconium is fused in an atm. of dry hydrogen, and rapidly cooled, it exhibits an effect like the *spitting* of silver in oxygen, and the metal may be left in a porous condition. Zirconium readily absorbs hydrogen, and

FIG. 2. — Dissociation Pressure of Zirconium Hydride.

L. Weiss and E. Neumann found that when a current of hydrogen is passed over powdered red-hot zirconium, a dark grey powder is formed with a composition approximating **zirconium dihydride,** ZrH_2, where the zirconium appears to be bi- not quadri-valent. It is contaminated with about 4 per cent. of zirconia. The product discolours the skin, and when heated in a test-tube, burns with incandescence, and some small detonations. The hydride is probably wholly decomposed at about 800°. The dissociation press. of the dihydride on a rising temp. were found to be rather smaller than on a falling temp., as shown in Fig. 2. A. Sieverts and E. Roell said that powdered zirconium, at different temp. and press., absorbs rather less hydrogen than is needed for the dihydride, and they assume that a solid soln., not a chemical compound, is formed.

Cooling . . .	99	100	107	308	752	— ,,

Amorphous or crystalline zirconium is stable in **air** at ordinary temp. If the powdered metal be heated in a test-tube and shaken into the air, the particles glow by oxidation, and similarly, if the powdered metal be dusted over a Bunsen's

flame, the particles glow brightly as they pass through the flame. According to J. J. Berzelius, the amorphous metal burns to the oxide if heated below redness; but, in agreement with the general observations that the compact crystalline metal is less chemically active than the amorphous variety, the metal which has been fused was found by L. Troost to be much more resistant, and, unless powdered, does not begin to oxidize quickly until it is heated white hot, indeed, he said that it required the oxy-hydrogen flame to start the combustion. These statements refer to the zirconium contaminated with aluminium, but E. Wedekind found that zirconium prepared with magnesium as the reducing agent is just as stable. L. Troost also found that the metal obtained with carbon as the reducing agent is quite stable in air at ordinary temp., and at a red heat, a little carbon may be oxidized superficially. If the zirconium be strongly carburetted, it burns with incandescence at a red heat. According to J. J. Berzelius, amorphous zirconium, ignited in vacuo and exposed to the air as soon as it cools, is pyrophoric. H. Moissan mentioned that an alloy contaminated with carbide and calcium carbide rapidly disintegrates in air. J. W. Marden and M. N. Rich found that a piece of the compact metal can be heated to bright redness in the blast-furnace with no more than a very thin, bluish, superficial oxidation, but when finely divided burns in air when heated to whiteness. According to E. Wedekind and S. J. Lewis, if the powdered metal be heated to 100° or 200° in air, it gradually increases in weight by the absorption of nitrogen, and oxygen. N. B. Pilling and R. E. Redworth studied the oxidizibility of zirconium. Most zirconium preparations when strongly heated give off ammonia. L. Troost found that crystalline zirconium resists the action of **oxygen** at a red heat; *une couche mince irisée d'oxyde* is formed on the surface protecting the rest of the metal from attack. He also found that the metal is very stable towards **water ;** there was no perceptible action after 12 hrs.' heating at 70°.

J. J. Berzelius showed that amorphous zirconium, and L. Troost, that crystalline zirconium, contaminated with aluminide, is rapidly dissolved by dil. or conc., hot or cold **hydrofluoric acid ;** and this acid is said to be *son véritable dissolvant.* A mixture of nitric and hydrofluoric acids, said J. J. Berzelius, dissolves amorphous zirconium with great rapidity. In general, said J. W. Marden and M. N. Rich, the compact metal is insoluble in all acids except aqua regia and hydrofluoric acid. According to H. Moissan, L. Troost, G. H. Bailey, A. Stähler and B. Denk, and L. M. Dennis and A. E. Spencer, **chlorine** or **bromine** vap. attacks the heated metal, forming the tetrahalide (*q.v.*). Liquid bromine acts but slowly; and **iodine** vap. is active, only at a high temp. L. Troost found that **hydrogen chloride** is decomposed when passed over the heated metal, and zirconium tetrachloride is formed. Cold **hydrochloric acid** does not act on zirconium, but, according to L. Troost, the conc. acid at 50°–100° acts very slowly on the crystalline metal contaminated with aluminide. Cold aqua regia acts very slowly; a gram of the metal required 5 hrs. to dissolve in an excess of this menstruum; a mixture of hydrochloric acid and potassium chlorate also acts slowly on the crystalline metal. J. J. Berzelius, H. Moissan and F. Lengfeld, and S. R. Paykull found that a mixture of powdered zirconium and **sulphur** reacts when heated over the gas burner. The metal is not attacked by cold **sulphuric acid,** but hot conc. sulphuric acid furnishes a little sulphur dioxide. According to C. A. Matignon, and E. Wedekind, zirconium at a temp. not exceeding 800°, reacts with **nitrogen,** forming the nitride ; with **ammonia** gas, under similar conditions, the nitride is formed ; the product does not give off ammonia in contact with cold water, but it does so with hot water. The metal is not attacked by cold or hot **nitric acid.** According to J. Gewecke, when a mixture of red **phosphorus** and zirconium is heated in an evacuated tube, the mass becomes incandescent, and a black powder is formed which is not attacked by water or dil. hydrochloric acid. M. Wunder and B. Jeanneret found that zirconium is dissolved in a few minutes when heated with **phosphoric acid** of sp. gr. 1·75 ; any carbon present remains undissolved. The addition of water or acid to the soln. produces

no precipitate. According to L. Troost, H. Moissan and F. Lengfeld, and J. J. Berzelius, when zirconium is heated with **carbon,** the carbide is formed; according to E. Wedekind, L. Troost, and H. Moissan, **silicon** forms a silicide; **silica** at a red heat is reduced by zirconium to silicon. According to S. A. Tucker and S. R. Moody, with **boron** a boride is formed; L. Troost and E. Wedekind found that **boric oxide** is not attacked when heated with zirconium. J. J. Berzelius said that a mixture of hydrated borax and zirconium explodes when heated owing to the action of zirconium on the oxygen of the water. J. W. Mallet found that when zirconium is heated in **cyanogen** gas, a dark brown powder is formed—possibly *zirconium carbonitride.* A. Korczynsky examined the catalytic action of zirconium or its halides on the halogenation of aromatic compounds.

According to L. Troost, **alkali hydroxides** attack crystalline zirconium contaminated with aluminium, and hydrogen is evolved, but the action occurs only when water is present. E. Wedekind found that purified zirconium is not attacked by soln. of the alkali hydroxides; there is a slight action with fused alkali hydroxides. J. J. Berzelius said that when a mixture of an alkali hydroxide, or **zirconium hydroxide** is heated, the reaction of zirconium with the oxygen of the water is explosive. The amorphous zirconium is slowly oxidized and dissolved by the fused alkali. He also said that when amorphous zirconium is heated with an **alkali carbonate,** it combines with the oxygen of the carbon dioxide with a slight explosion. Amorphous zirconium decomposes **potassium chlorate or nitrate** at a red heat, and a mixture of amorphous zirconium and potassium chlorate takes fire when struck, but not explosively. If a mixture of powdered zirconium and potassium nitrate be heated in a test-tube, a reaction sets in with explosive violence soon after the salt begins to melt. L. Troost said that his crystalline metal was not attacked by either potassium nitrate or chlorate. J. W. Marden and M. N. Rich said that the metal is not readily attacked by fused sodium hydroxide, **alkali hydrosulphates,** etc. J. J. Berzelius said that amorphous zirconium is readily dissolved by fused sodium hydrosulphate. A mixture of zirconium with the more easily reducible oxides—*e.g.* **cupric oxide, lead oxide,** etc.—explodes more or less violently when heated; but with the oxides which are reduced only with difficulty—*e.g.* **chromic oxide**—no reaction occurs at the temp. of the ordinary gas-flame.

Zirconium does not appear to alloy so readily with other metals as do silicon and titanium. H. S. Cooper made alloys of zirconium with *copper,* and with *gold.* J. W. Marden and M. N. Rich found that if silver be mixed with the other constituents in the preparation of zirconium by the thermite process, a *zirconium-silver alloy* is obtained. When the alloy containing 10–20 per cent. of silver is treated with acids, finely divided, cubic crystals are obtained. The alloy could not be made by the direct fusion of the two elements. C. Winkler, and E. Wedekind were unable to make a *zirconium-magnesium alloy.* Attempts to make a *zirconium-mercury alloy,* or *zirconium amalgam,* were failures. H. Davy passed a current through a slightly moistened zirconia anode arranged so that potassium amalgam served as the cathode. After some time, the amalgam furnished a white powder of zirconium when treated with water. Presumably a zirconium amalgam had been formed. E. Becquerel, and W. Kettembeil attempted to make the amalgam by the electrolysis of salt soln. with a mercury cathode, but the results were not successful. As previously indicated, the metal formerly called crystalline zirconium, prepared by L. Troost, was a *zirconium-aluminium alloy* containing 27 or more per cent. of aluminium. L. Troost made the alloy by heating potassium fluozirconate, or sodium chlorozirconate, in a carbon crucible to about 1500°. B. Franz, and S. Meyer made an alloy in a somewhat similar way—*vide* the preparation of zirconium by the aluminium process. These alloys were examined by E. Wedekind. They are said to resemble the corresponding aluminium-titanium alloys, but to require a higher temp. for their production; and they are also said to have a lower tensile strength. An alloy with 6 per cent. of zirconium exhibited the maximum tenacity of 12·5 kgrms. per sq. mm. H. Schirmeister measured the tensile strength of these

alloys. E. Wedekind found that in the preparation of zirconium by reducing the oxide or halogen salt with an excess of aluminium and treating the resulting mass alternately with potash-lye and hydrochloric acid, an **aluminium hemizirconide,** $ZrAl_2$ (or perhaps $ZrAl_3$), remains. This compound forms a mass of crystalline plates resembling antimony in appearance and fracture; it is not appreciably attacked by the simple acids though hot hydrofluoric acid or aqua regia dissolves it slowly. If the alloy be melted in the electric furnace, the **aluminium tritetritazirconide,** Zr_3Al_4, is formed; this compound is very hard, and resists attack by chemical agents. It is not certain if these zirconides are really chemical individuals.

J. W. Marden and M. N. Rich were unable to make a *zirconium-tin alloy* or a *zirconium-lead alloy* directly or indirectly. H. S. Cooper made pyrophoric alloys of zirconium and 20–40 per cent. of tin. N. Petinot made a zirconium-lead alloy by charging a mixture of zirconium and calcium carbide into molten lead. E. Podszus made *tungsten-zirconium* and *tantalum-zirconium alloys* by reducing the mixed oxides in a current of ammonia gas at a temp. high enough to dissociate the nitrides; and cooling rapidly to prevent the formation of nitrides. J. B. Grenagle [2] obtained a *zirconium-tantalum* and a *columbium alloy.* E. Wedekind made an alloy carrying about one per cent. of zirconium by heating a mixture of iron and zirconium in vacuo, and J. L. Brown and H. S. Cooper, and J. B. Grenagle obtained *ferrozirconium alloy,* containing 65 per cent. of zirconium, by reducing a mixture of the finely-divided oxides with aluminium, or by heating the mixed oxides in a graphite crucible in an electric furnace. The use of zirconium as a scavenger for removing oxides and nitrogen from steel has been patented by L. Weiss. It is said that zirconium steel, *i.e.* steel with a small percentage of zirconium, is very hard and useful in making armour plates, armour-piercing projectiles, and bullet-shields. It is claimed that an armour plate 1 in. thick is equivalent to a plate of the best German steel, 3 in. thick. F. M. Becket has discussed these alloys. H. S. Cooper has patented a number of complex *nickel-zirconium* alloys; *cobalt-zirconium* alloys; and self-hardening nickel alloys with from 2 to 40 per cent. zirconium and less than 35 per cent. chromium. F. M. Becket, R. H. McKee, J. W. Marden and M. N. Rich, A. L. Feild, and G. K. Burgess and R. W. Woodward also prepared a number of iron-zirconium alloys. Ferrozirconium, said M. Wunder and B. Jeanneret, is dissolved by hot phosphoric acid of sp. gr. 1·75, giving a clear soln.—*vide* zirconium. H. S. Cooper made an alloy with *nickel.*

The valency of zirconium.—In 1824, J. J. Berzelius gave zirconia the formula ZrO_3; but later altered it to Zr_2O_3 by analogy with alumina, Al_2O_3, etc. The sesquioxide formula was employed by R. Hermann, but L. Gmelin preferred ZrO by analogy with magnesia, MgO; beryllia, BeO, etc. In 1857, H. St. C. Deville and L. Troost, after they had shown that the vap. density of zirconium chloride agreed with the formula $ZrCl_4$, naturally proposed the formula ZrO_2, for the oxide on the assumption that zirconium is quadrivalent. This conclusion has been confirmed by W. Biltz and J. A. Clinch from the determinations of the mol. wt. of zirconium acetylacetonate by the b.p. method: by W. G. Mixter and E. S. Dana from measurements of the sp. ht. of zirconium; by C. H. Pfaff, G. Rose, J. C. G. de Marignac, and J. W. Retgers from the isomorphism between rutile and zirconia, and between the fluozirconates, fluosilicates, fluotitanates, and fluostannates; by B. D. Steele, from the position of zirconium in the periodic system; by L. F. Nilson and O. Pettersson, by the approximate agreement of the mol. hts. of the dioxides of zirconium, thorium, cerium, titanium, tin, and manganese; by the analogies between the chloroplatinates of zirconium, thorium, and tin, indicated by L. F. Nilson, and between the metacarbonates, R_2CO_3, metasilicates, R_2SiO_3, metatitanates, R_2TiO_3, and metazirconates, R_2ZrO_3—where R represents a univalent radicle; and by H. G. J. Moseley, and E. Friman from measurements of the X-ray spectra. The hydride, ZrH_2 (*q.v.*), shows that zirconium may be bivalent; but the existence of the monoxide, ZrO, is doubtful.

The atomic weight of zirconium.—The at. wt. of zirconium was first deter-

mined by J. J. Berzelius,[4] and from the analysis of the neutral sulphate, he inferred this to be 89·461 (O=16). R. Hermann obtained 89·354 from analyses of the oxychloride and the tetrachloride ; J. C. G. de Marignac, 90·536 from analyses of potassium zirconifluoride ; M. Weibull, 89·48 from analyses of the sulphate, and 90·13 from analyses of the selenate ; G. H. Bailey, 90·66 from analyses of the sulphate ; F. P. Venable, 90·80 from analyses of the oxychloride. F. P. Venable and J. M. Bell obtained the value 91·76 as an average of fourteen determinations of the ratio of $ZrCl_4 : Ag$ (chlorine, 35·458 ; silver, 107·88) ; the extreme variations were 91·95 and 91·62. F. W. Clarke gave 90·621 as the average of the different determinations available in 1910 ; and B. Brauner, 90·7. The International Table of at. wts. gives 90·6 as the best representative value. The survey of the at. wt. determinations by F. W. Clarke gave him the impression that " the at. wt. of zirconium needs careful revision," but even then, with the variations in the proportions of hafnium in samples of zirconium from different sources, it is remarkable that greater differences have not been observed. G. von Hevesy examined some historical preparations of zirconium salts in chemical museums and estimated that those used by J. J. Berzelius had 2 per cent. of hafnia ; those by R. Hermann, 1 per cent. ; those by J. C. G. de Marignac, 0·5 per cent. ; those by M. Weibull, 2·0 per cent. ; those by F. P. Venable and J. M. Bell, 0·7–1·0 per cent. ; and those by O. Hönigschmid, none. The presence of 1 per cent. of hafnia raises the at. wt. of zirconium by 0·6 unit. O. Hönigschmid and co-workers gave 91·22 for the value corrected for hafnium, from the ratio $ZrBr_4 : 4AgBr$, and $ZrBr_4 : 4Ag$. F. P. Venable and J. M. Bell corrected their results for hafnium and obtained 91·2 for the at. wt. of zirconium. This, said G. von Hevesy, agrees with the value 91·22 ± 0·1 of O. Hönigschmid, and this is the best representative value of the at. wt. of zirconium. The **atomic number** of zirconium is 40. F. W. Aston reported the three **isotopes** with at. masses 90, 92, and 94, with possibly another of at. mass 96. For the alleged degradation of zirconium to carbon, *vide* zirconium nitrate. The **electronic structure** of the atom was discussed by N. V. Sidgwick, C. P. Smyth, and J. Beckenkamp—*vide* hafnium. H. Pettersson and G. Kirsch obtained a little evidence of **atomic disintegration** when the atoms are bombarded by α-rays.

Reactions of analytical interest.—All aq. soln. of zirconium salts have an acid reaction owing to hydrolysis ; hence, the neutralization of a soln. is only temporary and approximate. According to G. J. Brush,[5] if turmeric paper be moistened with a hydrochloric acid soln. of a zirconium salt, and dried, it has a reddish-brown colour which is not produced by thorium salts. A. A. Noyes and co-workers said the colour is pink. If zirconium hydroxide be dissolved in hot hydrochloric acid, evaporated almost to dryness, digested with water, and treated with conc. hydrochloric acid in the cold, a basic chloride, $ZrOCl_2.8H_2O$, is precipitated. Otherwise hydrochloric acid, and hydrogen sulphide give no precipitation with zirconium salt soln. In what follows, an aq. soln. of zirconium sulphate is supposed to be employed unless otherwise stated. According to R. Hermann, and J. J. Berzelius, aq. soln. of **ammonia**, or of **ammonium sulphide,** furnish a white precipitate of the hydroxide, insoluble in excess. These precipitations, said J. J. Berzelius, are not prevented by ammonium chloride ; but, added E. A. Demarçay, if fluorides be present, the precipitation by ammonia is only partial. Aq. soln. of the **alkali hydroxides** furnish a similar precipitate, which, unlike the hydroxides of aluminium and beryllium, is insoluble in an excess of the reagent. The freshly precipitated hydroxide produced in cold soln. is readily soluble in dil. acids, but dissolves very slowly if produced in hot soln. Conc. acids, however, dissolve both precipitates quickly. **Ammonium carbonate** gives a white flocculent precipitate of basic carbonate, readily soluble in excess, but reprecipitated on boiling the soln. A similar precipitate, somewhat soluble in excess, and reprecipitated by ammonia, is produced by **alkali carbonates**. These properties were studied by J. J. Berzelius, A. Mandl, and R. Hermann. According to J. N. von Fuchs, **calcium carbonate** precipitates a carbonate from

zirconium salt soln., and, according to H. Rose, there is but an incomplete precipitation when **barium carbonate** is added, even if the soln. be boiled. Both **oxalic acid** and **ammonium oxalate** give a crystalline precipitate of zirconium oxalate when added to a soln. of zirconium chloride, but no precipitate is given by aluminium and beryllium salt soln. The precipitate is soluble in an excess of oxalic acid, and ammonium oxalate, but sparingly soluble in hydrochloric acid. The soln. in ammonium oxalate, unlike the thorium salt, does not give a precipitate with hydrochloric acid. Ammonia precipitates all the zirconium as hydroxide from the soln. in ammonium oxalate. L. N. Vauquelin, N. J. Berlin, R. Ruer and co-workers, F. P. Venable and J. M. Bell, E. Glaser, and others have studied the action of oxalates on zirconium salts. Soln. of **sodium sulphate** or **ammonium sulphate** do not give precipitations, but, according to J. J. Berzelius, with a cold conc. soln. of **potassium sulphate,** all the zirconium is slowly precipitated as a complex salt which, unlike the aluminium or beryllium salt, is insoluble in an excess. The precipitate produced with cold soln. is readily soluble in dil. hydrochloric acid ; but if produced in boiling soln., a basic sulphate is precipitated, which, unlike the thorium and cerium salt, is not soluble in dil. hydrochloric acid. According to J. F. Bahr, R. Hermann, M. Weibull, and A. Stromeyer, a soln. of **sodium thiosulphate** precipitates from the hot soln. all the zirconium as hydroxide mixed with sulphur. A feebly acid soln. of zirconium chloride, not the sulphate, gave a precipitate of the hydroxide when treated with **sulphur dioxide.** Unlike thorium and yttrium salt soln., zirconium salt soln. give no precipitation with **hydrofluoric acid**. A conc. soln. of **hydrogen dioxide** precipitates the zirconium as peroxide, $Zr(OH)_3.H_2O_2$, from slightly acid soln. I. T. Davis, and P. H. M. P. Brinton and C. James showed that a soln. of an **alkali iodate** gives a precipitate of zirconium oxyiodate preferably from hot soln. The precipitate is but sparingly soluble in water, in an excess of the precipitant, or in acids. F. P. Venable and I. W. Smithey used **iodic acid** in place of the iodate. According to L. Haber, **chromic acid** gives an orange-yellow flocculent precipitate, particularly in boiling soln. T. Curtius and A. Darapsky found that **sodium azide** completely precipitates zirconium as hydroxide from cold soln. **Phosphoric acid,** or **alkali phosphates,** give a white precipitate of zirconium phosphate. According to W. Biltz and W. Mecklenburg, if the soln. be strongly acidified with nitric or hydrochloric acid, and a few drops of a soln. of sodium phosphate added, and the liquid be warmed, a white gelatinous precipitate is produced even when as little as 0·0005 per cent. of zirconia is present. Iron, aluminium, rare-earth elements, beryllium, thorium, titanium, or silicon salt soln. do not give the precipitation in strongly acid soln.—vide hafnium, which also gives this reaction.

According to M. Dittrich and S. Freund, if a zirconium salt soln. be dropped into a boiling soln. of **sodium salicylate,** a precipitate of zirconium salicylate is formed—not so with titanium salts. According to H. Rose, A. Sjögren, R. Hornberger, J. J. Berzelius, and R. Hermann, a neutral soln. of zirconium chloride gives a white precipitate with **potassium ferrocyanide,** with acid soln. the precipitate is greenish-yellow. The precipitation is less complete in sulphate soln. In neutral sulphate soln. or acid chloride soln., H. Rose, and L. de Boisbaudran found that **potassium ferricyanide** gives a green precipitate ; with **potassium cyanide,** H. Rose found that zirconium hydroxide is precipitated. **Tartaric acid** precipitates zirconium tartrate incompletely, and the precipitate is soluble in an excess, or in sodium acetate soln. ; **alkali tartrates** give a white precipitate ; with **citric acid** or **malic acid,** L. Haber obtained results similar to those with tartaric acid. **Sodium acetate** gives a white flocculent precipitate with boiling soln. A white precipitate is produced with **alkali succinates and benzoates.** Numerous other precipitations and colorations with organic compounds have been examined by L. Haber, C. Vincent, B. F. Hartwell, S. H. Harris, A. Mandl, E. Rimbach and P. Schneider, H. Kaserer, A. Mc. M. Jefferson, A. Müller, and A. Rosenheim and P. Frank. **Ammonium nitrosophenylhydroxylamine,** $C_6H_5N(NO)ONH_4$, conveniently called

cupferron, was shown by O. Bandisch and V. L. King to give a quantitative separation of zirconium and aluminium ; it precipitates quantitatively iron and zirconium from a soln. of the mixed salts. The method was used by E. Ferrari, J. Brown, C. E. F. Lundell and H. B. Knowles, W. M. Thornton and E. M. Hayden, J. W. Marden and M. N. Rich, etc. E. T. Allen recommended **phenylhydrazine** in faintly acid soln. which precipitates alumina and zirconia quantitatively. G. von Knorre used **nitroso-β-naphthol** for separating zirconium and iron ; and I. Belluci and G. Savoia observed that coloured complex salts are produced by zirconium salts in acid soln. and α-nitroso-β-naphthol and β-nitroso-α-naphthol. F. Steidler found that various shades of brown are produced by zirconium and hafnium salts on linen or artificial silk dyed with **turmeric ;** and with **picric acid,** zirconium oxychloride gives a yellow precipitate of indefinite composition. J. H. de Boer found that salts of zirconium, titanium, aluminium, yttrium, cerium, erbium, thallium, columbium, tungsten, thorium, molybdenum, and uranium give a violet coloration with **alizarinsulphonic acid,** but the colour disappears on the addition of conc. hydrochloric acid with all except zirconium, and hafnium.

The uses of zirconium.—Zirconium and its compounds have some uses [6] in the arts and industries. The possible application of zirconium as a scavenger in steel, etc., has been previously discussed in connection with the zirconium alloys. The oxide has been used to replace the lime cylinders of the limelight—*vide* zirconia. Zirconia cylinders give a more intense illumination, and they are not affected by the moisture and carbon dioxide of the atm., which rapidly deteriorate lime cylinders. The early incandescent mantles made by A. von Welsbach [7] contained much zirconia, but a mixture of thoria and other rare earths is now used almost exclusively. The glower or filament of W. Nernst's lamp contain much zirconia, as well as thoria, etc. The mixture conducts the current electrolytically, and not like the metal and carbon filaments. The electrochemical decomposition at the electrodes is rendered harmless by the oxidizing action of air. Hence these lamps do not burn in vacuo. A single oxide is not so good a conductor nor so luminous as a mixture of oxides. Oxides are used because they are so stable, and the rare-earth oxides are used as they have a higher m.p. than other oxides. Since the luminous efficiency rises with the temp. the most infusible oxides possible are employed. Just as thoria alone has a much lower efficiency than a mixture of thoria with one per cent. of ceria, so zirconia alone is much less efficient than a zirconia rod containing a little thoria, ceria, or similar oxide. The rod or filament does not conduct at a low temp. but only when heated, hence Nernst's lamp has a supplementary coil to heat the filament externally whereby it becomes a good conductor. The luminous efficiency is stated to be 0·85 per cent. and the cost 0·004 pence per candle-power hour.

Zirconia is used in the manufacture of highly refractory [8] crucibles, muffles, resistance cores, etc. Ware made from zirconia not only resists high temps., but it also withstands many fluxes, slags, acids, and fused alkalies very well. If properly bonded with 3 to 10 per cent. of clay or magnesia, and fused in an electric furnace at about 2000°, ware made from zirconia is not easily broken, and is almost impervious to liquids ; it has a low coefficient of thermal expansion, and, like fused silica, does not therefore readily crack with sudden changes of temp., but, unlike fused silica, it does not readily devitrify. Firebricks made from zirconia with a bonding refractory clay, sodium silicate, magnesia, borates, phosphates, etc., require burning at a very high temp. in order that the bricks may not shrink unduly in use. Tests with such bricks on the hearth of a steel furnace are reported to have given excellent results. The use of zirconia for this purpose has not come up to expectations because in many furnaces the conditions are highly reducing, and zirconia disintegrates owing to the formation of carbide. As indicated above, the reaction begins about 1400°, but the actions may possibly be more difficult with the silicate. The use of purified zirconia and other compounds of zirconia in place of stannic oxide, antimony oxide, etc., as an opacifying agent [9] for glazes and

enamels or glazes for glazed bricks, tiles, sanitary ware, and enamelled iron has been the subject of many patents, and mixtures are sold under various names— *e.g. terrar*, etc. The results are good with the right type of glaze or enamel. The use of zirconium in the manufacture of filaments for electric lamps [10] has been patented but has not been successful; the carbide has also been recommended as an abrasive [11] since it is nearly as hard as topaz. The use of zirconium compounds —oxide, silicate, carbonate, basic sulphite, and phosphate—as pigments has been patented.[12] The paints are reputed to have a good covering power and to be non-poisonous. The basic acetate is sold as *Konstrastin* for weighting silk; [13] and as a mordant in dyeing and in the preparation of lac-dyes,[14] and the oxide has been used in place of bismuth nitrate for defining the intestines for making X-ray photographs of the abdomen.[15] Zircon is used in making the knife-edges and planes for balances on account of its hardness. According to C. Willgerodt,[16] the chloride can be used as a catalytic agent for chlorinations in making aniline dyes, etc.

§ 7. The Zirconium Oxides

Five oxides of zirconium—ZrO; Zr_2O_3; ZrO_2; Zr_2O_5; and ZrO_3—have been reported, but evidence of the existence of the dioxide is alone satisfactorily definite. This oxide, ZrO_2, corresponds with other oxides of the members of the fourth group of the periodic classification, namely, CO_2, SiO_2, TiO_2, CeO_2, SnO_2, etc. A true bill seems to have been made out for the existence of a hydrated form of the trioxide, $ZrO_3.nH_2O$.

When zirconium is reduced with magnesium, and freed from magnesia and the excess of magnesium by washing with acids, an insoluble powder remains which has been reported by C. Winkler,[1] L. M. Dennis and A. E. Spencer, and E. Wedekind to consist largely of **zirconium monoxide**, ZrO; and in some cases a product containing oxygen almost eq. to ZrO has been obtained. It is said that the monoxide reacts less vigorously with chlorine than the metal, and if it were amorphous metal it would react more quickly being in a finer state of subdivision—unless, of course, the granules have protective surface films of dioxide; the sp. gr. is also said to be lower than that of an eq. mixture of finely divided metal and zirconia—the sp. gr. of zirconia, however, itself depends on the mode of preparation. The readiness with which the product obtained by reducing zirconia with magnesium is oxidized has been taken to show that a product more sensitive to oxygen than zirconium is present, but a pyrophoric condition is not unusual with metals in a finely divided state. W. H. Whitney and co-workers also cited the cataphoresis of the alleged zirconium monoxide as an argument in favour of the individuality of zirconium monoxide, but E. Wedekind's experiments do not agree with this, for the behaviour of colloidal zirconium seems to vary with the mode of preparation. The work of R. Schwarz and H. Deisler, and E. Wedekind has shown that it is highly probable that the supposed existence of zirconium monoxide—analogous with titanium monoxide, TiO—is a mal-inference from the analytical numbers obtained with what are really mixtures of zirconium metal and zirconia. The alleged monoxide gives volatile zirconium chloride, $ZrCl_4$, when treated with chlorine and in amounts corresponding with the presence of 31 per cent. of free zirconium, whereas non-volatile, $ZrOCl_2$, would have been anticipated had the monoxide been really present. The decrease in weight which occurs when the alleged monoxide is heated to 250° in chlorine, and the gain in weight when heated in oxygen, are in harmony with this assumption. By the combustion of the hydride, ZrH_2, L. Weiss and E. Neumann obtained a greenish-white powder, analyses of which agree with **zirconium sesquioxide**, Zr_2O_3. This compound passes very slowly into the white dioxide, ZrO_2, when calcined in air. Here again evidence of chemical individuality is lacking. G. H. Bailey also reported **zirconium hemipentoxide**, $Zr_2O_5.nH_2O$, to be formed as a white precipitate when an acid soln. of zirconium disulphate is treated with 30 per cent. hydrogen dioxide. According to H. Geisow and P. Horkheimer, the alleged compound is probably partly decomposed zirconium trioxide, $ZrO_3.nH_2O$ (q.v.).

In 1892, L. Fletcher [2] reported the occurrence of monoclinic crystals of zirconia, ZrO_2, in the gem-bearing sands of Rakvana (Ceylon), and, almost simultaneously, E. Hussak reported the occurrence of a tantalo-columbate in the pyroxenitic sands from Jacupiranga (South Brazil); L. Fletcher named the Ceylonese mineral **baddeleyite**—after J. Baddeley—and E. Hussak called the Brazilian mineral *brazilite.* The latter term was subsequently abandoned in favour of baddeleyite. After E. Hussak had reported the analysis of brazilite and L. Fletcher that of baddeleyite, it became clear that the two minerals were chemically the same :

	ZrO_2	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	$K_2O(Na_2O)$	Loss on ignition.
Brazilite	96·52	0·70	0·43	0·41	0·55	0·10	0·42	0·39
Baddeleyite	96·37	0·59	0·13	0·37	0·21	—	—	0·98

Baddeleyite is a constituent of the *jacupirangite* found by O. A. Derby in the magnetitic pyroxenites of Jacupiranga, Saõ Paulo, Brazil. The same mineral has also been reported by A. F. Rogers near Bozeman, Montana ; by E. Hussak at Alnö, Sweden ; by G. P. Tschernik, from Kuda Padi Oya, India ; and by F. Zambonini at Mt. Somma, Vesuvius. Analyses have also been reported by G. S. Blake and G. F. H. Smith, L. Weiss, E. Wedekind, and R. Bayer. Large zirconia deposits occur on an undulating plateau in the Caldas region, partly in the States of Minas Geraes and Saõ Paulo, Brazil. Several large outcrops of the ore occur west of the plateau, where there are boulders weighing 30 tons. The massive ore, which occurs in fibrous, botryoidal, or columnar forms, is not baddeleyite, but rather a mixture of at least three minerals : baddeleyite, zircon, and an unnamed zirconium silicate which, on treatment with dil. hydrofluoric acid, passes into soln. along with the baddeleyite and leaves behind small crystals of zircon as a residue. The term *zirkite* has been registered as a trade name for zirconia ore. The massive ore occurs in various tints ranging from light grey, reddish-brown, to bluish-black ; the dark-coloured varieties show the largest proportion of zirconia ; some of the lighter-coloured material shows a minimum of about 70 per cent. zirconia. Alluvial pebbles, called *favas* —from the Portuguese *fava*, a bean—ranging up to 3 in. in diameter occur along small stream beds and the talus slopes of the lower ridges. The pebbles carry over 90 per cent. of zirconia oxide ; their sp. gr. ranges from 4·8 to 5·2. L. Weiss and R. Lehmann's analyses of different samples are indicated in Table I. An

TABLE I.—ANALYSES OF ZIRCONIA ORE.

	Red and friable.	Pale red and hard.	Reddish-black, hard.	Grey and very dense.	Vitreous or glassy.
Zirconia, ZrO_2	80·54	87·99	88·97	93·12	95·46
Silica, SiO_2	6·21	5·89	5·87	3·06	1·35
Titanic oxide, TiO_2	0·12	0·74	0·96	0·69	0·76
Alumina, Al_2O_3	3·07	0·84	0·93	0·54	0·51
Ferric oxide, Fe_2O_3	9·03	3·78	3·54	3·03	2·84
Loss on ignition, H_2O	2·01	0·54	0·51	0·07	—

approximately uniform grade with about 80 per cent. zirconia, ZrO_2, is obtained by sorting the crude ore. Amongst the elements of minor importance which have been reported in the ore are traces of the ceria earths, scandium, vanadium, and molybdenum. G. von Hevesy and V. T. Jantzen found 1 to 2 per cent. of hafnia to be present. According to A. von Antropoff, Brazilian zirconia earth is radioactive, and when heated in vacuo with sulphuric acid, furnishes argon and helium gases.

A pulverulent or granular form of **zirconia,** or **zirconium dioxide,** ZrO_2, is produced when the metal, the hydride, nitride, carbide, hydroxide, or the salt of a volatile acid, is heated in air, or oxygen. Zirconia, however, is usually extracted from zircon, baddeleyite, eudialyte, or other minerals rich in zirconia and as free as practicable from other impurities. The methods of extraction have been previously described. H. St. C. Deville and H. Caron [3] obtained small dendritic crystals, resembling those of ammonium chloride, by the action of boric oxide on zirconium fluoride heated in a carbon crucible. The reaction is symbolized : $3ZrF_4 + 2B_2O_3 = 3ZrO_2 + 4BF_3$; the boron fluoride is volatilized. A. E. Nordenskjöld obtained tetragonal crystals isomorphous with cassiterite, rutile, and thoria by melting zirconia with borax in a pottery oven. Analogous results were obtained by G. Wunder, W. Florence, A. Knop, and F. P. Venable and A. W. Belden. Similar results were reported by G. Wunder, and W. Florence by melting zirconia in fused microcosmic salt, but this does not agree with the observations of M. H. Klaproth, and F. P. Venable and A. W. Belden. L. Troost and L. Ouvrard obtained a phosphate under very similar conditions ; but they found that if the oxide, chloride,

phosphate, or other compound of zirconium be dissolved in fused normal potassium phosphate mixed with a little potassium chloride, and heated to a very high temp., much of the potassium and phosphoric oxide is volatilized, and quadratic prisms of zirconia remain. These crystals were not isomorphous with those of thoria. L. Ouvrard obtained lamellar hexagonal crystals of zirconia by cooling a soln. of zirconia in fused potassium carbonate ; and A. Michel-Lévy and L. Bourgeois, and J. Morozewicz obtained a similar result with fused sodium carbonate. K. A. Hofmann and K. Höschele obtained white tetragonal crystals from a soln. of zirconia in fused magnesium chloride ; under other conditions, L. Bourgeois obtained magnesium metazirconate, $MgZrO_3$. H. Moissan fused zirconia in the electric arc-furnace and obtained a vitreous mass with dendritic crystals of zirconia. P. Haute-feuille and A. Perrey found that hydrogen chloride at atm. press. has no action on zirconia at a high temp., but under a press. of 3 atm. and at a temp. below dull redness, rhombic plates of zirconia are formed. At the same temp. and at atm. press., hydrogen chloride was found to have a mineralizing effect on zirconium carbonate, oxalate, and sulphate, but not on the oxide. The crystallization is attributed to successive formations and decompositions of a hydrochloride.

The physical properties of zirconium dioxide.—The **colour** of purified zirconium oxide is white ; that of baddeleyite varies with the amount of ferric oxide which is present. In thin sections, baddeleyite is colourless, yellow, or brown ; the colour may be zonally or irregularly variable, and it occasionally exhibits the hour-glass structure. O. Hahn studied the surface area of the particles of precipitated zirconia in terms of adsorbed radioactive matter. E. Hussak [4] found the **crystals** of baddeleyite to belong to the monoclinic system and to have the axial ratios $a:b:c=0.9871:1:0.5441$, and $\beta=81° 30'$; G. S. Blake and G. F. H. Smith gave $0.9905:1:0.5110$, and $\beta=80° 32'$. So far as can be gathered from the meagre descriptions, probably the crystals obtained by P. Hautefeuille and A. Perrey, and W. Florence, also belonged to the monoclinic system ; while those obtained from fused borax, etc., by A. E. Nordenskjöld, G. Wunder, A. Knop, F. P. Müller, and A. Michel-Lévy and L. Bourgeois, belonged to the tetragonal system. A. E. Nordenskjöld gave for the axial ratios $a:c=1:1.0061$. The crystals of zirconium dioxide are therefore dimorphous, and possibly, according to J. W. Retgers, isodimorphous with those of silicon dioxide. H. Rose discussed the isomorphism of rutile, zirconia, silica, and stannic oxide. E. Hussak and J. Reitinger described favas occurring at Minas Geraes in reniform crusts, fibrous and concentric, which they regarded as an independent modification of zirconium dioxide, and not as a fibrous variety of baddeleyite. According to E. Hussak, the **habit** of the euhedral crystals of baddeleyite is tabular parallel to the (100)-face ; the crystals usually show **twinning,** most commonly about the (100)-plane ; there is also polysynthetic twinning ; and both contact and penetration twins with lamellæ parallel to (110), but rarely parallel to (201). The **cleavage** of baddeleyite parallel to (001) is nearly perfect, and that parallel to (010), less so. There is a parting parallel to (110), in consequence of lamellar twinning. The **corrosion figures** with cold dil. hydrofluoric acid were examined by E. Hussak. L. Vegard, and W. P. Davey, J. Böhm and H. Niclassen, and J. Böhm studied the **X-radiogram** of zirconia, but the available data are not capable of establishing the structure —*vide* rutile ; A. E. van Arkel said that the oxide has the same structure as fluorite with $d_{100}=5.86A$. M. L. Huggins inferred that, in the tetragonal crystal, each zirconium atom is surrounded by four equidistant oxygen atoms, and each oxygen atom by two equidistant zirconium atoms, all at the tetrahedral corners. L. Fletcher found that the **optic axial angle** is large, varying from $2E=70°-75°$.

For the **specific gravity** of baddeleyite, E. Hussak gave 5.006, and L. Fletcher, 6.025. For artificial crystals, A. E. Nordenskjöld gave 5.710–5.742 ; G. Wunder, 5.42–5.52 ; L. Ouvrard, 4.9 ; E. Podszus, 5.89 ; and A. Michel-Lévy and L. Bourgeois, 5.726. For artificial zirconium dioxide, L. N. Vauquelin gave 4.35 ; and

N. J. Berlin, 4·90. These numbers are too low, probably on account of the inadequate washing of the precipitate before calcination. R. Hermann gave for the artificial dioxide, 5·45 ; A. Sjögren, 5·50 ; F. P. Venable and A. W. Belden, 5·49 ; L. F. Nilson and O. Pettersson, 5·85 ; L. Bradford, 5·89 ; and R. Ruer, 5·65–5·66. R. Lehmann gave 4·9695 at 17·5° for the sp. gr. of the raw dioxide, 5·482 at 18·5° for that of the purified dioxide, and 5·75 at 15° for that of the fused oxide. G. von Hevesy and V. Berglund found that the sp. gr. of zirconia and hafnia prepared by igniting the respective sulphates at 1000°, are 5·73 for zirconia, 9·67 for hafnia at 20°. The hafnia content of zirconia can be fairly accurately calculated from the sp. gr. G. von Hevesy, and F. A. Henglein compared the mol. vol. of titanium, zirconium, hafnium, thorium, and cerium oxides. H. Moissan said that the sublimed zirconia forms small, white, rounded masses of sp. gr. 5·10 ; and that the transparent parts are hard enough to scratch glass. L. Fletcher gave for the **hardness** of baddeleyite, 6·5, and E. Hussak, 5·54. P. Berthier, and L. N. Vauquelin found that when hard lumps of the hydroxide are ignited the product scratches glass ; and, added H. Davy, it will even scratch rock-crystal. V. Bodin found that briquettes made from zirconia have a **crushing strength,** F kgrms. per sq. cm.

	20°	800°	1000°	1300°	1500°
F	395	275	345	90	10

thus showing a maximum at about 1100°, as is the case with clay briquettes.

M. Mayer and B. Havas measured the cubical coeff. of the **thermal expansion** and obtained $3a=0·0_42785$. R. Lehmann found between 20° and 210°, $3a=0·0_59855$ for the crude oxide, and $0·0_5251$ for the purified fused oxide ; this makes the coeff. of linear expansion of the purified dioxide $a=0·0_684$ when that of fused quartz is about $0·0_67$. The **thermal conductivity** is low. J. W. Marden and M. N. Rich say that it is about the same as that of fused quartz. L. F. Nilson and O. Pettersson gave 0·1076 for the **specific heat** of amorphous zirconia, and 13·13 for the **molecular heat.** L. Bradshaw and W. Emery found:

	0°–100°	25°–600°	25°–1000°	25°–1200°	25°–1400°
Sp. ht.	0·108	0·137	0·157	0·167	0·175

L. N. Vauquelin's zirconia fused at the heat of a smith's forge ; as pointed out by J. J. Berzelius, it must have been contaminated with potash because he could not fuse it at any temp. then accessible. H. Moissan fused it in the electric arc-furnace. O. Ruff and co-workers gave 2585° for the **melting point ;** and a specimen of 98·75 per cent. ZrO_2 melted at 2565° ; A. Stansfield gave 2500°–2950° for the m.p. ; W. R. Mott, 2500° ; E. Podszus, 2950°–3000° ; F. Henning, 2687° ; and E. W. Washburn and E. E. Libman gave 2700°—*vide* zirconium silicate. H. Moissan found that zirconia readily sublimes in the electric arc-furnace and furnishes a sublimate with a number of rounded white particles. O. Ruff and co-workers observed that the vaporization of zirconia is small at the m.p., and that silica distils from zirconia at 2000° under reduced press. W. R. Mott gave 4300° for the **boiling point** of zirconia. F. Born estimated zirconia to be dissociated into metal and oxygen to the extent of 10^{-11} at 2000°, and about 0·6 at 3000°. J. J. Berzelius found that the zirconia becomes insoluble in acids and acquires a higher sp. gr. after being heated, and H. Davy showed that the exothermal change produces a glowing—**calorescence** —which is more marked than is the case with alumina (*q.v.*), so much so, that " even at an incipient red heat, the zirconia becomes incandescent and appears as if it had taken fire." J. Böhm showed by X-radiograms that the phenomenon is connected with the passage from the amorphous to the crystalline state.

According to M. E. Chevreul, the calorescence is preceded by a blackening of the mass, but R. Hermann showed that this arises from the presence of impurities. According to R. Ruer, the incandescence appears at about 300°, and only when the hydroxide has been dehydrated at a lower temp. than this and while it still retains less than 1·9 per cent. of water. He also measured the heating curve shown

in Fig. 3, where the dotted line represents the course of the heating provided no singularity occurred. From the rise of temp. and the sp. ht. of zirconia, he calculated that the recalescence is attended by the evolution of over 9·2 Cals. per gram of zirconia. At higher temp., there are small explosions attended by the evolution of an extremely fine powder; and this phenomenon is the cause of losses in the ignition of zirconia in analytical work. L. Weiss and E. Neumann gave 175·5 Cals. per gram-atom for the **heat of formation** of the oxide from the metal; W. G. Mixter made some observations on this subject.

According to E. Hussak, the **index of refraction** and the **birefringence** of baddeleyite are high. C. P. Smyth discussed the relation between the refractivity and electronic structure of zirconium. The **optical character** is negative. The **pleochroism** is marked, being α, reddish-brown, β, oil-green, and γ, reddish-brown. In 1820, R. Hare in an attempt to fuse zirconia in the

FIG. 3.—Heating Curve of Zirconium Oxide.

oxy-hydrogen flame, noted the brilliancy of the light, and in 1826, T. Drummond found that when zirconia is heated in the oxy-hydrogen flame, it emits a very brilliant light. The relative intensities of lime, zirconia, and magnesia were stated to be respectively 37, 31, and 16 times the intensity of the light from an argand burner. The use of these agents for illuminating purposes was patented by G. H. Smith in 1862; H. Caron said that the light is about one-sixth as intense as that furnished by magnesia. A. W. Hofmann, however, pointed out that the zirconia is more durable than lime. According to E. Linnemann, the light is attended by the emission of very little heat, and the spectrum is continuous. The **light emissivity** of zirconia was studied by C. M. T. du Motay, W. E. Forsythe, A. Bettendorff, J. Philipp, E. Waller, J. W. Draper, W. Huggins, J. T. Taylor and W. H. Harrison, C. E. Mendenhall and L. R. Ingersoll, F. Schröter, H. Landolt, A. Payen, W. Kochs, G. P. Drossbach, and A. W. Hofmann. E. L. Nichols and co-workers investigated the blue glow which occurs when zirconia is heated in the oxy-hydrogen flame. According to W. W. Coblentz, purified zirconia is not an efficient radiator of white-light, and becomes so only when a small amount of cerium oxide or thorium oxide is added. With purified zirconia, there are two sharp emission bands with maxima respectively at $2·78\mu$ and $4·3\mu$. There are smaller maxima at 2μ, $2·4\mu$, $3·2\mu$, $4·7\mu$, and $5·4\mu$, Fig. 4. H. E. Ives and co-workers

FIG. 4. — Ultra-red Emission Spectrum of Zirconia.

measured the emissivity and illuminating power of mantles made of zirconia and heated by the bunsen flame. The **reflecting power** of zirconium oxide used as a pigment for light of different wave-lengths is:

λmax.	$0·54\mu$	$0·60\mu$	$0·95\mu$	$0·95\mu$	$4·4\mu$	$8·8\mu$	24μ
Per cent.	82·2	85·8	84·1	83·0	23·2	5·1	5·4

E. L. Nichols and D. T. Wilbur, and J. Ewles studied the luminescence of zirconia exposed to the **cathode rays**; E. L. Nichols and D. T. Wilbur, the **thermoluminescence** of zirconia. According to C. Kästle, zirconium dioxide and the zirconium salts are opaque to the **X-rays,** hence its possible use in place of bismuth nitrate for defining the intestines for X-ray photographs of the abdomen. J. Ewles found zirconia exhibits a faint blue cathodoluminescence; and E. L. Nichols and H. L. Howes studied the **flame luminescence** of zirconia. H. J. Spanner studied the emission of electrically charged ions by zirconia.
The **electrical conductivity** of zirconia is low, and the **electrical resistance** is quoted by J. W. Marden and M. N. Rich to be $1·2 \times 10^3$ ohms per cubic centimetre at 1200°. According to K. Angström, zirconia is diamagnetic, and S. Meyer gives $-0·003 \times 10^{-6}$ for the **molecular magnetism ;** and G. von Hevesy gave for the magnetic susceptibility $-0·112 \times 10^{-6}$ units per gram.

The chemical properties of zirconium dioxide.—Early attempts by J. B. Trommsdorff,[5] and H. Davy to reduce zirconia were not successful. Many of the ordinary reducing agents are ineffective ; **hydrogen** fails ; but, according to L. E. Barton, the oxide is partially reduced when heated in a reducing flame ; and it begins to dissociate about its m.p. E. Newbery and J. N. Pring found that zirconia is not reduced by hydrogen at 150 atm. press. at 2000°. F. Wöhler found that when zirconia is mixed with carbon and heated in **chlorine** or **bromine** vap., the tetrahalide is formed ; and F. Bourion, and A. Rosenheim and J. Hertzmann showed that the tetrachloride is formed when zirconia is heated in a mixture of chlorine and the vapour of **sulphur chloride,** S_2Cl_2. E. F. Smith and H. B. Harris found that the vapour of **phosphorus pentachloride,** or of **carbon tetrachloride** or **carbonyl chloride** converts heated zirconium dioxide into the tetrachloride (*q.v.*). According to J. J. Berzelius, the affinity of zirconia for **acids** is very slight ; the dioxide which has been heated to incandescence dissolves very slowly in hot **sulphuric acid,** for if zirconia be finely powdered, and digested in a hot mixture of 2 parts of sulphuric acid and one part of water, and then heated until the water and excess of acid are expelled, the residue contains soluble zirconium sulphate. F. P. Venable and A. W. Belden found that when dil. sulphuric acid, sp. gr. 1·56, is heated with powdered zirconia, only 0·672 per cent. of its weight of the oxide is dissolved. R. Ruer made some observations on the dissolution of zirconia in sulphuric acid. J. J. Berzelius said that the ignited oxide is slowly dissolved by **hydrofluoric acid ;** and F. P. Venable and A. W. Belden found that strongly ignited zirconia is easily dissolved by hot hydrofluoric acid. According to F. P. Venable and T. Clarke, a little zirconia is dissolved during prolonged digestion with **hydrochloric acid.** E. Podszus said that zirconia dissolves in hydrochloric acid when the particles are less than 1μ ; S. A. Tucker and H. R. Moody, and E. Wedekind found that zirconia is reduced when mixed with **boron** and heated in an electric furnace, zirconium boride is formed ; and E. Wedekind and co-workers found that with **silicon,** zirconium silicide is formed. H. C. Greenwood, and J. N. Pring showed that with **carbon** the reduction of zirconia begins at about 1400°. C. Renz found that, unlike titania, zirconia is not photosensitive in the presence of organic liquids. F. P. Venable and T. Clarke said that zirconia is not attacked by molten **boric oxide.** H. Davy did not succeed in reducing zirconia satisfactorily with **potassium** G. H. Bailey, T. L. Phipson, and E. Wedekind reduced zirconia by heating it with **magnesium,** and an alloy was formed ; E. Wedekind reduced zirconia by **calcium ;** and S. A. Tucker and H. R. Moody found the reduction with **aluminium** is unsatisfactory, an alloy is formed. Zirconia is readily dissolved by fused **alkali hydroxides** producing a zirconate ; and with molten **alkali carbonates** carbon dioxide is evolved and a zirconate is formed ; molten **alkali and alkaline earth chlorides** form zirconates ; and fused **alkali hydrosulphates** and fused **potassium hydrofluorides** furnish soluble zirconium salts ; when zirconium dioxide is moistened with a soln. of a **cobalt salt** and calcined, it assumes a dirty violet colour. S. Medsforth examined the effect of zirconia on nickel as a catalyst in the reduction of carbon monoxide and dioxide by hydrogen ; A. Mailhe and F. de Godon, as a catalyst in esterifications ; and P. Sabatier and A. Mailhe, as a catalyst in dehydrating alcohol. For the uses of zirconia, *vide* zirconium.

The zirconium hydroxides.—A white, voluminous, gelatinous precipitate is obtained when a soln. of ammonia, alkali hydroxide, ammonium sulphide, or potassium cyanide is added to a soln. of a zirconium salt. The precipitate is usually regarded as a **zirconium hydroxide,** $Zr(OH)_4$, or **orthozirconic acid,** H_4ZrO_4. Unlike **yttrium** hydroxide, the precipitation of zirconium hydroxide is prevented

if tartaric acid be present. R. Ruer said that the hydroxide appears to be more voluminous if precipitated from hot soln. than from cold soln. The composition varies with the conditions under which it is formed. As observed by L. N. Vauquelin,[6] when the precipitate dries, it shrinks and forms a yellowish-white, shining, translucent, gum-like mass with a conchoidal fracture. The freshly precipitated hydroxide, washed with cold water, was found by J. M. van Bemmelen to contain 95 per cent. of water, corresponding with $ZrO_2.127H_2O$, and after drying in air, 47 per cent. of water, corresponding with $ZrO_2.6H_2O$. After drying in vacuo, H. Davy, and S. R. Paykull found numbers in agreement with $ZrO_2.1\frac{1}{2}H_2O$; and after drying over conc. sulphuric acid, R. Hermann, and A. Mandl obtained numbers corresponding with $ZrO_2.2H_2O$; after washing with petroleum ether, F. P. Venable and A. W. Belden found the composition nearly the same, $ZrO_2.2H_2O$; and after washing with alcohol and ether, J. M. van Bemmelen found the composition, $ZrO_2.0\cdot7H_2O$ to $ZrO_2.0\cdot8H_2O$. J. J. Berzelius, and S. R. Paykull found that the hydroxide dried at $100°$ has a composition corresponding with $ZrO_2.H_2O$, and, added R. Ruer, the same result is obtained whether the precipitated hydroxide be formed in hot or cold soln. A. Mandl obtained a similar result at $110°$, and J. M. van Bemmelen at $140°-200°$. The latter also found that at $300°$ the composition approximates $ZrO_2.0\cdot6$(to $0\cdot7)H_2O$. For the recalescence which occurs when heated, *vide supra*, zirconium dioxide. The hydroxide dried over sulphuric acid at $65°$, and having the composition $ZrO_2.2\cdot7H_2O$, after heating to different temp. contained, according to J. M. van Bemmelen, $ZrO_2.nH_2O$:

	$80°$	$100°-110°$	$140°$	$200°$	$260°-280°$	$7280°$
n . . .	$2\cdot0$	$1\cdot9-1\cdot6$	$1\cdot08$	$1\cdot0$	$0\cdot6-0\cdot7$	$0\cdot6-0\cdot2$

The hydroxide behaves as a gel up to about $140°$ because the proportion of water varies continuously with the temp., and the vap. press. of the water vap. Between $140°$ and $200°$, the proportion of water is constant, and corresponds with $ZrO_2.H_2O$, or **metazirconic acid,** H_2ZrO_3, or **zirconyl hydroxide,** $ZrO(OH)_2$. This metazirconic acid is not the same as that obtained by R. Ruer—*vide infra*. The evidence is not decisive enough to affirm that a definite hydrate is formed, because the product still possesses an absorptive power. In the so-called *chemical hydrates*, the dehydration proceeds in stages and is reversible except when a simultaneous change in structure makes the change irreversible ; with the *colloidal hydrates*, the composition depends on the structure of the colloid, and varies continuously with changes of temp. or press. J. M. van Bemmelen found that the dehydration is only partially reversible because less water is taken up when the partly dehydrated product is rehydrated. Thus, in an atm. over sulphuric acid diluted to a conc. eq. to the vap. press. p mm. of steam, when the composition is represented by n mols of H_2O per mol of ZrO_2,

p . . .	.	.	.	.	9	8	6	4	2
n {Dehydration	.	.	.	.	6	5	5	4	3
{Rehydration	.	.	.	.	←	4	3	3	3←

The power of rehydrating becomes less and less each time the hydrated dioxide is dehydrated. R. Ruer found that the gelatinous precipitate obtained by adding aq. ammonia to a soln. of metazirconium (*i.e.* zirconyl) chloride, is less voluminous than that obtained from the normal chloride, and its composition corresponds with metazirconic acid ; when dried at $100°$, its composition is $ZrO_2.\frac{2}{3}H_2O$, and if boiled for some time its composition approximates $ZrO_2.\frac{1}{3}H_2O$. When heated, it forms ordinary zirconium dioxide without becoming incandescent. According to F. P. Venable and A. W. Belden, the sp. gr. of the hydroxide precipitated in the cold, and approximating $ZrO_2.2H_2O$, is $3\cdot25$. F. Haber observed no difference in the X-radiograms of zirconia soln. and precipitated zirconia ; both gave weak interference rings. H. T. S. Britton studied the electrometric precipitation of the hydroxide. A soln. of zirconium oxychloride slowly yields a precipitate when

treated with sodium acetate; but not with the tetrachloride; zirconia is precipitated from the chloride or sulphate before the acidity has been reduced to $p_H=10^{-2}$, which acetic acid can barely attain in conc. soln. No precipitation occurred during the titration of 100 c.c. of $0.01M$-$ZrCl_4$ with $0.1N$-sodium acetate, and the acidity of the soln. ranged from $p_H=3.15$ to 4.81. With $0.1N$-sodium oxalate no precipitation occurred with zirconium sulphate, and with 100 c.c. of $0.01M$-$ZrCl_4$ a gelatinous precipitate occurred with 10 c.c. of the sodium oxalate. With $0.1N$-sodium tartrate and 100 c.c. of $0.01M$-$ZrCl_4$ a basic tartrate was precipitated when 10 c.c. of tartrate had been added, and $p_H=1.66$, but it began to dissolve with 30 c.c. of tartrate, and the soln. was clear with 42.5 c.c. of tartrate.

F. P. Venable and A. W. Belden said that the hydrated dioxide is quite insoluble in water. The earlier workers, e.g. D. E. Melliss, said that it is slightly soluble in water, 100 parts of water dissolving 0.2 part of the dioxide. The aq. soln. was said to have an acid reaction; the alleged alkalinity towards turmeric has been attributed to the incomplete removal of alkali in the washing. In fact, if precipitated with an alkali, it is almost impossible to remove the adsorbed alkali by washing. According to J. J. Berzelius, J. B. Hannay, A. Sjögren, E. Linnemann, R. Ruer, A. Mandl, F. P. Venable and A. W. Belden, and O. Hauser, if the hydrated dioxide is precipitated and washed in the cold, it dissolves readily in hydrochloric, hydrobromic, nitric, sulphuric, or oxalic acid, and less readily in acetic, tartaric, or citric acid; but if the hydrated dioxide has been precipitated hot, or washed with boiling water, it dissolves only slowly in the conc. acids; but after a prolonged digestion the amount dissolved is the same with hydrated dioxide precipitated hot or cold. According to J. B. Hannay, the hydrated dioxide derived from zircons of high sp. gr. dissolves more slowly in oxalic acid than that derived from zircons of low sp. gr. S. R. Paykull said that it absorbs carbon dioxide from the air, and when heated in a current of this gas, 16.4 per cent. was absorbed, and most of this was given off again in a current of air. F. P. Venable and T. Clarke said that the hydrated dioxide is sparingly soluble in conc. alkali-lye, and almost insoluble in dil. alkali-lye. A litre of 50 per cent. potassium hydroxide dissolved 2.23 grms., and a litre of 33 per cent. sodium hydroxide dissolved 2.45 grms. F. P. Venable and A. W. Belden found that the hydrated dioxide is not perceptibly soluble in aq. ammonia of sp. gr. 0.90; and that 100 parts of aq. ammonia of sp. gr. 0.96, dissolve 0.01 part ZrO_2. J. J. Berzelius said that the hydrated dioxide is insoluble in boiling aq. soln. of ammonium salts. F. P. Venable and A. W. Belden showed that 100 parts of a sat. soln. of ammonium carbonate dissolve one part of the hydrated dioxide, while a soln. of ammonium tartrate dissolves rather less. R. Hermann stated that the hydrated dioxide is insoluble in soln. of alkali carbonates.

Zirconium hydroxide exhibits a tendency to polymerization, forming a series of hydroxides exhibiting different properties. In addition to the normal hydroxide obtained by treating a soln. of zirconyl chloride, or zirconium sulphate with ammonia, R. Ruer reported the formation of metazirconic acid when a soln. of zirconyl chloride is boiled—vide metazirconic chloride. There is also the hydroxide obtained by E. H. Rodd by adding ammonia to a soln. of zirconium octoxytetrachloride or octoxydisulphate. If this hydroxide be dissolved in hydrochloric acid, the soln. furnishes crystals of the octoxytetrachloride, a soln. of the ordinary hydroxide in the same acid furnishes zirconyl chloride. The hydroxide from the octoxytetrachloride is therefore regarded as having a constitution analogous to the basic chloride, namely, $Zr_5O_8(OH)_4$, or $Zr(O.ZrO.OH)_4$, or $ZrO_4(ZrO.OH)_4$, tetrahydroxyzirconyl zirconate. There is evidence of a partial decomposition of this compound by hydrochloric acid, because the last crop of crystals from the soln. is a mixture of $Zr_5O_8Cl_4$ and $ZrOCl_2$. Ordinary zirconium sulphate is produced by dissolving this hydroxide in sulphuric acid.

According to A. Lottermoser, the **hydrosol** of zirconium hydroxide is not formed by the dialysis of a soln. of the chloride, by the digestion of the hydroxide in water, nor of zirconia obtained from zirconium oxalate; but, according to W. Biltz, it

can be obtained by the dialysis of zirconium nitrate, oxychloride, or acetate. W. Müller made it in the following manner :

Three grams of zirconium nitrate are dissolved in water, and precipitated in the cold with aq. ammonia ; and washed with cold water to remove the ammonia. The precipitate is then mixed with an aq. soln. of 10 grms. of zirconium nitrate for 15 mins. in the cold ; heated for 15 mins. on a water-bath ; and then boiled. The filtered liquid is opalescent, and on evaporation furnishes a clear gum which swells up in water, forming a viscid soln. The liquid becomes turbid on dilution.

R. Ruer made the hydrosol by dialyzing a soln. of zirconium oxychloride, or zirconyl chloride ; and A. Rosenheim and J. Hertzmann, by the dialysis of a 1·5 per cent. soln. of zirconium acetate. The hydrosol obtained from zirconyl chloride soln. contains a chloride which is not directly precipitated by silver nitrate soln., and which is protected in some way by the colloid. On attempting to remove the last traces of chloride, a hydrogel is formed. The chloride is " accessible " to the silver nitrate after the soln. has been boiled with nitric acid—*vide infra*, metazirconic chloride. The zirconium hydroxides previously described are considered to be **hydrogels.**

W. Biltz found that the hydrosol is fairly stable when boiled, and when treated with electrolytes ; and it is positively charged against water. W. Biltz and co-workers gave 0·046 to 0·09 for the gold number (**3.** 23, 8) ; P. Behre gave 0·05. The hydrosol prepared by dialyzing a soln. of zirconyl nitrate is clear in transmitted light, but cloudy in reflected light. When the hydrosol of orthozirconic acid is boiled, it forms the hydrosol of metazirconic acid ; and the opalescent liquid which is formed has been likened to the hydrosol of metastannic acid. According to W. Müller, the less ionized univalent salts have no effect on the hydrosol, but the strongly ionized salts cause coagulation ; salts of higher valency also cause flocculation ; the anions are active, the cations negligible. A. Rosenheim and J. Hertzmann obtained similar results with a clear hydrosol obtained by hydrolyzing zirconium acetate. B. Szilard obtained colloidal zirconium hydroxide almost free from electrolytes by decomposing a soln. of a zirconium salt with an excess of dil. aq. ammonia, and washing the residue for 3 to 6 days until it is quite free from ammonia. The product is a fine milky suspension in which the particles cannot be separated either by filtration or decantation ; it is precipitated by electrolytes and by the carbon dioxide of the air. B. Szilard also found that zirconium hydroxide can be peptized by uranyl nitrate, furnishing a yellow, turbid, opalescent, very stable soln. O. Ruff and J. Moczala studied the adsorption of zirconium nitrate, and of nitric, hydrochloric, phosphoric, and sulphuric acids by zirconia ; and the production of plastic masses of zirconia for making vessels of various kinds. W. Pauli considered the hydrogels are complexes : $Zr(OH)_4.Zr(OH)_2Cl_2$, etc. H. Freundlich and E. Schalek measured the viscosity and elasticity of colloidal soln. of zirconium hydroxide ; E. Schalek and A. Szegvari, the rate of coagulation of the sol of zirconium hydroxide ; and E. Wedekind and H. Wilke, adsorption and coagulation of the sol prior to chemical reaction with hydrogen dioxide, arsenious acid, arsenic acid, and phosphoric acid. The adsorption of dyes by zirconia gel was found by H. Rheinboldt and E. Wedekind to resemble the phenomenon with silica gel. They also examined the adsorption of phosphoric and boric acids, as well as of molybdenum-blue, and starch iodide soln. M. Adolf and W. Pauli found that sols of zirconia are coagulated by electrolytes only when the conc. exceeds $0·25N$. The dried soln. was found by J. Böhm and H. Niclassen to furnish X-radiograms characteristic of amorphous substances, but, on ageing, the gel becomes crystalline.

According to P. T. Cleve,[7] when ammonia is added to a soln. of zirconium sulphate containing hydrogen dioxide a gelatinous **hydrated zirconium peroxide,** $Zr(OH)_3O.OH$, is precipitated : $Zr(OH)_4+HO.OH=H_2O+Zr(O.OH)(OH)_3$. G. H. Bailey obtained a higher oxide by adding a conc., feebly acid soln. of the sulphate. The object of the acid was to avoid the possible presence of zirconium

hydroxide produced in the presence of an excess of ammonia. G. H. Bailey regarded his product as a pentoxide, $Zr_2O_5.nH_2O$, but H. Geisow and P. Horkheimer consider this to be a stage in the decomposition of the trioxide. A. Piccini did not obtain such precipitates, and H. Geisow and P. Horkheimer suggested that Piccini's soln. were too dil. ; they confirmed P. T. Cleve's results using a 30 per cent. hydrogen dioxide soln. and an alkaline soln. E. Wedekind obtained the peroxide by mixing an alkaline soln. of a zirconium salt, in the presence of alkali tartrate, with hydrogen dioxide. L. Pissarjewsky obtained a similar product by the action of an aq. soln. of sodium hypochlorite upon zirconium nitrate : $Zr(NO_3)_4 + NaOCl + 4H_2O = NaCl + Zr(OH)_3O.OH + 4HNO_3$, at a temp. not exceeding $10°$; and, by electrolyzing an aq. soln. of sodium chloride in which zirconium hydroxide is suspended ; the sodium chloride is converted into sodium hypochlorite, which acts as an oxidizing agent. The oxidation is an endothermal process : $Zr(OH)_4 + O = Zr(OH)_3(O.OH) - 21.78$ Cals. The gelatinous precipitate is rather unstable, and loses oxygen on standing. With dil. sulphuric acid, hydrogen dioxide is formed, and ozonized oxygen with the conc. acid. According to L. Pissarjewsky, the hydrated peroxide dissolves in potassium hydroxide soln. containing hydrogen dioxide, and the addition of alcohol to the soln. at about $3°$, precipitates **potassium perzirconate**, $K_4Zr_2O_{11}.9H_2O$; and similarly with **sodium perzirconate,** $Na_4Zr_2O_{11}.9H_2O$. G. H. Bailey regarded the hydrated peroxide as a derivative of a zirconium pentoxide, $Zr_2O_5.4H_2O$; others have supposed it to be a derivative of a *zirconium trioxide*, $ZrO_3.nH_2O$; and others again have suggested that $Zr(OH)_3(O.OH)$ is an intermediate stage in the peroxidation of the tetrahydroxide, $Zr(OH)_4$, on the way to the tetraperzirconate $Zr(O.OH)_4$.

§ 8. The Zirconates

Zirconium dioxide, or hydrated zirconium dioxide, is amphoteric in that it acts both as an acid and as a base. There are three main types of zirconium salts : (i) The *normal salts* in which the zirconium behaves as a quadrivalent radicle, in combination with the radicles of the stronger acids. (ii) A series of *basic salts* in which, in the simplest case, the bivalent radicle ZrO, **zirconyl,** acts as a base. These salts can often be regarded as but stages in the progressive hydrolysis of the normal salts. (iii) A series of zirconates or rather **metazirconates** in which zirconyl hydroxide, $ZrO(OH)_2$, acts as an acid, **metazirconic acid,** H_2ZrO_3. There is a tendency for the acid to form poly-zirconates analogous with the poly-silicates, and poly-titanates. The poly-zirconates can be named like the poly-silicates. The *perzirconates* are described in connection with perzirconic acid—*vide supra*.

The alkali zirconates are formed either by adding a soln. of a zirconium salt to alkali-lye, or by melting zirconium oxide with the alkali oxide, hydroxide, carbonate, or chloride, with boric oxide as a flux and *agent minéralisateur*. The products obtained in this manner have not a definite composition and are probably zirconates contaminated with more or less adsorbed base or acid. Both M. E. Chevreul,[1] and P. Berthier stated that when zircon and potassium hydroxide are fused together a *potassium silicozirconate* is produced (*q.v.*) ; L. Ouvrard, and D. E. Melliss also obtained the silicozirconates by fusing zircon with potassium carbonate ; but A. Knop found that when zircon is fused with potassium or sodium carbonate, the corresponding alkali zirconate remains when the cold mass is extracted with water to remove the soluble alkali silicate. L. Ouvrard obtained only crystalline zirconia by this procedure. F. P. Venable and T. Clarke showed that it is not practicable to prepare the potassium zirconates by the action of fused potassium carbonate on zirconia because only 0·5 per cent. dissolved after 10 hrs.' heating— but the amount dissolved must be largely determined by the temp. P. Hautefeuille and J. Margottet found that when potassium carbonate and zirconium phosphate are melted together, and then extracted with water, there remains insoluble

potassium zirconate. According to J. J. Berzelius, by melting zirconia with potassium hydroxide, a **potassium zirconate,** insoluble in water and soluble in acids, is formed. F. P. Venable and T. Clarke showed that this zirconate is probably a poly-salt, $K_2O(ZrO_2)_{3\ to\ 5}$, because if treated with acetic acid, the insoluble mass corresponds approximately with $K_2O(ZrO_2)_3$, or **potassium paratrizirconate,** $K_2Zr_3O_7$. According to R. Hermann, and F. P. Venable and T. Clarke, the addition of potassium hydroxide to a soln. of a zirconium salt gives a precipitate containing 3 to 4 per cent. of alkali; F. P. Venable and T. Clarke found that zirconium hydroxide, $ZrO_2.H_2O$, dissolves in a soln. of potassium hydroxide:

KOH per cent.	.	.	.	.	.	12 25 33 50
ZrO_2 grms. per litre		.	.	.	.	0·09 0·75 0·90 2·30

and they accordingly inferred that the soln. contained potassium zirconate. They also found that a definite potassium zirconate is not obtained by fusing a mixture of potassium chloride and zirconia as in T. Hiortdahl's and L. Ouvrard's processes for the alkaline earth zirconates; but J. J. Berzelius showed that when zirconia is dissolved in fused sodium hydroxide, it is not thereby rendered soluble in water, which merely washes away the excess of alkali; and that, as in the corresponding case of potassium hydroxide, a **sodium zirconate** appears to be formed because the zirconia is thereby made soluble in acids. W. Gibbs, D. E. Melliss, and L. Bourgeois obtained *sodium silicozirconates* (*q.v.*) by the action of fused sodium carbonate on zircon; but T. Scheerer could get only sodium zirconate. T. Hiortdahl heated zirconia with sodium carbonate, and measured the amount of carbon dioxide evolved. When equimolar proportions of the two were kept at a dull red heat for 9 hrs., all the available carbon dioxide was evolved, and there remained a crystalline hygroscopic mass which he assumed to be **sodium metazirconate,** Na_2ZrO_3; this was decomposed by water yielding sodium hydroxide and an insoluble white mass mainly zirconium oxide. If an excess of sodium carbonate be used, he found that the molar proportions of carbon dioxide evolved per mol. of zirconia were:

						Dull redness.	Bright redness.	Yellow heat.	White heat.
Hours	.	.	.	.	.	23	5½	5½	6
$ZrO_2.nCO_2$	.	.	.	.	.	1·20	1·41	1·45	1·92

Hence he concluded that **sodium orthozirconate** is formed, $2Na_2O.ZrO_2$, or Na_4ZrO_4. If this product be treated with water, sodium zirconate is obtained in hexagonal plates with a composition approximating $Na_2O.8ZrO_2.12H_2O$. Similar results were obtained when zircon was fused with an excess of sodium carbonate. R. Hermann, and T. Scheerer concluded that sodium zirconate is formed when a mixture of zircon and sodium carbonate is fused, and the cold mass extracted with water. By a similar process, A. Michel-Lévy and L. Bourgeois obtained rhombohedral plates of sodium zirconate accompanied by much crystallized zirconia. F. P. Venable and T. Clarke found that when zirconia is added to clear melted sodium carbonate, it sinks to the bottom and remains unattacked for hours. After leaching the cold fused mass with water, and treatment with dil. hydrochloric acid, the product contained soda and zirconia in the molar proportions $Na_2O : ZrO = 2 : 3$; and in another case, where the fusion occupied twice as long, the ratio was 3 : 2. When sodium hydroxide was fused in place of the carbonate, a much larger proportion of zirconia took part in the reaction.

According to L. Ouvrard, when a mixture of lithium chloride and zircon or zirconia is fused for some hours, and the mass extracted with water, prismatic crystals with a longitudinal extinction, and the composition of **lithium metazirconate,** Li_2ZrO_3, are formed. F. P. Venable and T. Clarke add that the mixture must be kept at a high temp., because with an ordinary fusion there is very little action. So also when lithium carbonate and zirconia are fused together, carbon dioxide is evolved, and zirconia crystallizes from the melt. F. P. Venable and C. Baskerville melted a mixture of zirconia and lithium hydroxide, and after extracting the mass with water and acetic acid obtained a residue corresponding

with **lithium mesodizirconate,** $Li_2Zr_2O_5$. It is noteworthy that while the alkalies soda and potash have a great tendency to form polyzirconates, the alkaline earths gave the normal metazirconates ; and lithium oxide represents a kind of transition between the alkalies and alkaline earths.

According to P. Berthier, when a mixed soln. of cupric and zirconium salts is treated with ammonia, the precipitate of the zirconium hydroxide carries down with it cupric hydroxide which cannot be extracted by ammonia. The sky-blue precipitate becomes emerald-green on ignition. The precipitate gives up most of its cupric oxide to ammonium carbonate soln., but not to oxalic or acetic acid. There is nothing to show that a *copper zirconate* is formed.

L. B. G. de Morveau obtained a coherent mass by igniting a mixture of zirconia and calcium oxide. According to T. Hjortdahl, a crystalline powder of an acid calcium zirconate is formed when a mixture of calcium chloride in excess and zircon, or zirconia and silica, is heated for 5 or 6 hrs. at bright redness, and the cold product washed with dil. hydrochloric acid. L. Ouvrard obtained **calcium metazirconate,** $CaZrO_3$, by heating a mixture of zirconia and fused calcium chloride for 20 to 30 hrs. After leaching with water, a crystalline mass remained. G. Tammann gave 950° for the temp. of formation. F. P. Venable and T. Clarke found that the reaction during the fusion occurs only after calcium oxide has been formed ; and they obtained the same compound by heating a mixture of zirconia and calcium oxide for many hours, and washing the product with dil. acetic acid. The crystals found by L. Ouvrard have a marked action on polarized light and appeared to be isomorphous with calcium metastannate and perowskite or calcium metatitanate. L. Ouvrard prepared **strontium metazirconate,** $SrZrO_3$, by fusing zirconia and strontium chloride ; the reaction is not so easily inaugurated as in the case of calcium metazirconate. F. P. Venable and T. Clarke made it by heating a mixture of zirconia and strontium oxide, leaching the product with dil. acetic acid. The crystals resemble those of the calcium salt, and are quite soluble in dil. hydrochloric acid. L. Ouvrard, and F. P. Venable and T. Clarke made **barium metazirconate,** $BaZrO_3$, by processes analogous to those they employed for the strontium and calcium salts. The properties were similar. G. Tammann gave 300° for the temp. of formation. J. A. Hedvall and N. von Zweigbergk could not make barium zirconate by heating a mixture of zirconia and barium dioxide.

According to T. Hiortdahl, if a mixture of silica, zirconia, ammonium chloride, and an excess of magnesium chloride be fused at a white heat for an hour, a mass of hemihedral crystals of periclase, and prismatic crystals of **magnesium metazirconate,** $MgZrO_3$, are formed ; and they are isolated by leaching the cold cake with water. L. Bourgeois also described the preparation of this salt. F. P. Venable and T. Clarke obtained the prismatic crystals by heating a mixture of zirconia and four times its weight of magnesia, and leaching the mass with dil. acetic acid. G. Tammann gave 980° for the temp. of formation of **zinc zirconate,** $ZnZrO_3$; and 700°, for that of **lead zirconate,** $PbZrO_3$.

L. B. G. de Morveau fused together a mixture of alumina and zirconia. K. von Chroustchoff heated in a closed steel tube a mixture of gelatinous silica, gelatinous alumina, and gelatinous zirconium hydroxide. It was subjected to a gradually increasing heat for six days, and allowed to cool. The residue in the crucible was then found to consist of a white powder, in part distinctly crystalline. The crystals exhibited, under the microscope, hexagonal forms, and had a sp. gr. of 2·87. The analysis corresponds with $2Al_2O_3.ZrO_2.8SiO_2.4H_2O$; and K. von Chroustchoff likens it to a *zirconopyrophyllite.*

A black or dark brown mineral found associated with baddeleyite at Jacupiranga, Brazil, was named by E. Hussak and G. T. Prior [2] zirkelite—after F. Zirkel—although the same name had been previously applied to a rock by M. E. Wadsworth. The analysis

ZrO_2	TiO_2	ThO_2	Ce_2O_3	Y_2O_3	UO_2	FeO	CaO	MgO	Ignition
52·89	14·95	7·31	2·52	0·21	1·40	7·72	10·79	0·22	1·02

corresponds with $(Ca,Fe)O.2(Zr,Ti,Th)O_2$. In the idealized case the mineral is a **calcium ferrous mesozirconate,** $Ca_2FeZr_2O_5$. The octahedral crystals belong to the cubic system, but G. S. Blake and G. F. H. Smith described the zirkelite crystals from Walaweduwa, Ceylon, as being probably hexagonal with $a : c = 1 : 1·1647$, and suggest

that the Brazilian crystals are probably hexagonal or rhombohedral rather than cubic. P. Groth, and O. Hauser consider that like titanite a cubic modification is produced by melting the mineral. E. Hussak and G. T. Prior said that the crystals exhibit polysynthetic twinning ; spinel twinning ; and fourlings. The crystals are flattened and striated. There is no visible cleavage. The sp. gr. of Brazilian zirkelite is 4·706 to 4·741, and of the Singalese, 4·72 to 5·22. The hardness is 5·5 to 6·0.

O. Hauser found a black or dark brown mineral on the shore of Magad Lake, East Africa, and called it **uhligite**. This analysis corresponds with $3.3Ca(Zr,Ti)_2O_5,Al(Ti,Al)O_5$. It is related to zirkelite. The crystals belong to the cubic system ; the habit is octahedral ; and the cleavage cubic and imperfect.

§ 9. Zirconium Fluoride, and the Fluozirconates

According to J. J. Berzelius,[1] hydrofluoric acid dissolves zirconia until the liquid no longer has an acid taste. The soln. furnishes a crystalline salt when evaporated, and the product is resolved by water into a soluble acidic salt, and an insoluble basic salt. When the soln. is boiled, there is a further deposition of basic salt, and the liquid becomes still more acid. This description refers to **trihydrated zirconium fluoride**, $ZrF_4.3H_2O$; and it was made by J. C. G. de Marignac by heating ammonium fluozirconate to drive off the ammonium fluoride, dissolving the residue in hydrofluoric acid, and evaporating the soln. for crystallization. Anhydrous zirconium tetrafluoride, ZrF_4, was made by H. St. C. Deville by passing hydrogen chloride over a mixture of zircon and calcium fluoride contained in a carbon boat in a carbon tube heated to whiteness ; and H. St. C. Deville and H. Caron made it by passing hydrogen fluoride over zircon heated to whiteness as before. J. C. G. de Marignac, and J. Missenden made it by heating a mixture of zirconium dioxide with twice its weight of ammonium fluoride, or hydrofluoride. This method, said L. Wolter, has the disadvantage that this substance volatilizes more readily than it attacks the zirconium dioxide. This, however, can be overcome by using, instead of ammonium hydrofluoride, ammonium fluozirconate, $ZrF_4.2NH_4F$, which is readily prepared in a pure state by evaporating zirconium dioxide with excess of silica-free hydrogen fluoride and ammonia, and subliming the product in a platinum tube in a current of nitrogen. He found that theoretical yields of zirconium tetrafluoride of a high degree of purity are obtained by the action of anhydrous hydrogen fluoride on zirconium tetrachloride, the change readily taking place in accordance with the equation $ZrCl_4 + 4HF = ZrF_4 + 4HCl$.

L. Wolter's product was snow-white and crystalline ; and when sublimed, zirconium tetrafluoride forms small, strongly refracting, prismatic crystals with slightly curved facets. H. St. C. Deville said that the crystals probably belong to the hexagonal system. L. Wolter found the sp. gr. to be 4·4333 at 16°. The salt was found by H. St. C. Deville to be volatile. This agrees with E. Wedekind's observation that in analytical work, when a mixture of zirconia and silica is ignited

with hydrofluoric acid to remove silica, some zirconium is lost by volatilization as fluoride. The loss is prevented by using a mixture of hydrofluoric acid and an excess of sulphuric acid. L. Wolter showed that the vap. density of zirconium tetrafluoride, 166·1, is in agreement with 166·7 calculated for the mol. wt. of ZrF_4. Zirconium tetrafluoride was stated by H. St. C. Deville to be insoluble in water, and acids ; but L. Wolter said that, unlike the other members of the carbon family, zirconium tetrafluoride is only sparingly soluble in water, 100 c.c. of water dissolve 1·388 grms. of the tetrafluoride, and he added that there is no sign of hydrolysis. When the aq. soln. is warmed to 50°, the trihydrate, $ZrF_4.3H_2O$, is precipitated, and no other hydrate or oxyfluoride was formed. With liquid ammonia, zirconium tetrafluoride forms a white powder of **zirconium hemipentitammino-tetrafluoride,** $5ZrF_4.2NH_3$, whilst with gaseous ammonia, pyridine, hydrogen sulphide, etc., practically no change takes place. It is suggested that the inactivity of the zirconium tetrafluoride compared with other members of the group is perhaps due to its small mol. vol. : TiF_4, 44·3 ; ZrF_4, 37·5 ; SnF_4, 40·7 It is assumed that with zirconium tetrafluoride the same number of atoms are condensed to a smaller vol., and hence the atoms have less freedom of motion. Zirconium tetrafluoride forms numerous complex salts with the metal fluorides, the so-called **fluozirconates,** R_2ZrF_6 ; but there are many fluozirconates more complex than this, the normal type.

The crystals of trihydrated zirconium tetrafluoride were found by J. C. G. de Marignac to be prismatic or tabular, and to belong to the triclinic pinacoidal system, having the axial ratios $a:b:c=0.7636:1:0.6390$, and $a=104°$ 48′; $\beta=110°$ 59′; and $\gamma=103°$ 53′. When heated, the crystals lose water and hydrogen fluoride, and even at a temp. below redness, furnish zirconia. According to E. A. Demarçay, ammonia precipitates only part of the zirconium as hydroxide in the presence of ammonium fluoride ; and when ammonia is added to the aq. soln., J. C. G. de Marignac said that part of the zirconium is precipitated as hydroxide, and part as a basic salt. J. J. Berzelius' observations on the hydrolysis of the aq. soln. of zirconium tetrafluoride are not in agreement with those of L. Wolter ; E. Chauvenet goes further, and argues the fact that the alleged trihydrate can be redissolved and recrystallized from water time and again is no proof that the hydrolysis does not occur ; he believed that the so-called trihydrate, $ZrF_4.3H_2O$, is really a hydrate of an acid zirconyl fluoride, namely, **dihydrated zirconyl dihydrofluoride,** $ZrOF_2.2HF.2H_2O$. He said that the salt is stable in air and in vacuo, but begins to lose water at 100° ; at 140°, in dry air, it loses two mols. of water, giving the anhydrous acid fluoride, which, when heated above 140° in air, loses two mols. of hydrogen fluoride, giving **zirconyl fluoride,** $ZrOF_2$; this, when cold, reabsorbs two mols. of hydrogen fluoride. The anhydrous normal zirconyl fluoride may also be obtained by crystallizing the hydrated acid fluoride from dil. aq. soln. and drying the **dihydrated zirconyl fluoride,** $ZrOF_2.2H_2O$, at 120°. If the anhydrous or hydrated acid fluoride is heated at 200° in an atm. of hydrogen fluoride, zirconium fluoride, ZrF_4, is obtained, which, in the cold, absorbs hydrogen fluoride, probably to form **hydrofluozirconic acid,** H_2ZrF_6. When dried and calcined, the salt furnishes zirconia.

According to H. L. Wells and H. W. Foote, the complex fluorides with fluorides of the alkali metals of small at. wt. give types with a relatively larger number of mols. of the alkali fluorides, while those of larger at. wt. give complex fluorides with a larger proportion of zirconium fluoride. This is illustrated by the following summary of the complex salts with the univalent radicles :

						4 : 1	3 : 1	5 : 2	2 : 1	5 : 3	1 : 1	2 : 3
Li	.	.	.	.	.	Li	—	—	Li	—	—	—
Na	.	.	.	.	.	—	—	Na	Na	—	—	—
K	.	.	.	.	.	—	K	—	K	—	K	—
Rb	.	.	.	.	.	—	Rb	—	Rb	—	—	—
Cs	.	.	.	.	.	—	—	—	Cs	—	Cs	Cs
NH₄	.	.	.	.	.	—	NH₄	—	NH₄	—	—	—
Tl	.	.	.	.	.	—	Tl	—	—	Tl	Tl	—

J. C. G. de Marignac found that when a mixed soln. of ammonium and zirconium tetrafluoride is evaporated, rhombic bipyramidal crystals of **ammonium fluozirconate,** $(NH_4)_2ZrF_6$, separate in the earlier stages of the evaporation; and in the later stages thin, tabular, hexagonal crystals appear. The salt is therefore dimorphous. The rhombic crystals have the axial ratios $a : b : c = 0.5739 : 1 : 0.6590$, and are isomorphous with those of the corresponding potassium salt. The hexagonal crystals were stated by B. Gossner to have a perfect cleavage parallel to the c-axis, and to have a feebly negative optical character. Ammonium fluozirconate is not changed when heated to 100°, but at a higher temp., ammonium fluoride is evolved, and zirconium tetrafluoride remains. G. von Hevesy and co-workers found the solubility of ammonium hexafluozirconate in water to be :

	0°	20°	45°	90°
Mols NH_3 per litre . . .	1·226	2·115	3·680	5·93
Mols Zr per litre . . .	0·611	1·050	1·842	2·96

The sp. gr. of the soln. at 20° is 1·154. This fluozirconate is decomposed when heated with sulphuric acid. J. C. G. de Marignac obtained another complex salt, **ammonium heptafluozirconate,** $3NH_4F.ZrF_4$, or $(NH_4)_3ZrF_7$, by evaporating a soln. of zirconium tetrafluoride containing a large excess of ammonium fluoride. G. von Hevesy gave for the refractive index of the octahedral crystals of ammonium heptafluozirconate, 1·433. The regular octahedral crystals are not changed when heated to 100°. O. Hassel and H. Mark studied the X-radiogram of the salt, and found the unit cubic cell has a side of 9·35 A., and contains 4 mols. The salt is isomorphous with the corresponding hafnium compound. These two ammonium fluozirconates have compositions analogous with those of the two ammonium fluotitanates; but the salts are not isomorphous. G. von Hevesy and co-workers found the solubility of ammonium heptafluozirconate in water to be represented at 0°, by 1·230 and 0·425 mols respectively of NH_3 and Zr per litre; at 20°, by 1·756 and 1·588 mols.; and at 45°, by 2·357 and 0·788 mols. The sp. gr. of the soln. at 20° is 1·086. For a litre of soln. of the heptafluozirconate in ammonium fluoride at 20° :

Mols NH_4F	Mol NH_3	Mol Zr	Sp. gr.
0·002	1·655	0·551	1·086
0·462	1·125	0·375	—
0·966	0·726	0·242	—
1·941	0·292	0·0942	—
4·872	0·0678	0·0226	1·068
9·721	0·0515	0·01716	1·105

The results for mixed soln. of ammonium hexa- and hepta-fluozirconate in water at 20° are plotted in Fig. 5. The solid phases are indicated in the diagram. Comparisons of the solubilities of the two ammonium fluozirconates with the corresponding ammonium fluohafniates are shown in Figs. 1 and 3 in the next chapter on hafnium. M. M. Windsor prepared double fluorides with aniline, brucine, cinchonine, quinine, quinidine, and strychnine.

H. L. Wells and H. W. Foote made **lithium fluozirconate,** Li_2ZrF_6, by mixing soln. containing 0·7 to 2·0 grms. of lithium fluoride and 20 grms. of zirconium tetrafluoride. The hexagonal crystals show the prism and pyramid, and rarely the basal plane. These investigators also mixed soln. containing 5 to 7 grms. of lithium fluoride and 20 grms. of zirconium tetrafluoride, and obtained ill-defined crystals of **lithium octofluozirconate,** $4LiF.ZrF_4.\frac{3}{2}H_2O$. The lithium fluoride has a low solubility, and it was not possible sufficiently to concentrate soln. to obtain the double salt of a high degree of purity either with hot or cold soln. One crop of crystals contained both the 2 : 1 and the 4 : 1 salts, showing that there is probably no intermediate salt. The salt is decomposed by water, and the soln. furnishes lithium fluoride. Normal **sodium fluozirconate,** Na_2ZrF_6, was also obtained in very minute crystals of hexagonal outline by mixing 1 to 2 parts of

sodium fluoride with 14 parts of zirconium tetrafluoride. The salt decomposes when the attempt is made to recrystallize it from water. The analysis indicated 0·50 to 1·96 per cent. of water "probably mechanically included " in the crystals. J. C. G. de Marignac prepared **sodium tridecafluodizirconate,** $5NaF.2ZrF_4$, by double decomposition of sodium chloride and ammonium fluozirconate, or by mixing soln. of the component salts under widely varying conditions. The salt can be recrystallized from water. The crystals were said to be monoclinic prisms with axial ratios $a : b : c$ =2·108 : 1 : 1·516, and β=97° 13'. The crystals show twinning. H. L. Wells and H. W. Foote reported that the crystals resemble those of olivine, and the habit appears to be rhombic consisting usually of stout prisms made up of two prismatic planes terminated by a steep brachydome ; less frequently the front pinacoid is broadly developed and the prisms are small. The optic axial angle is large, and the birefringence small. J. C. G. de Marignac found that the crystals suffer no loss in weight at a red heat ; and that 100 parts of water at 18° dissolve 0·387 part of salt ; and at 100°, 1·67 parts of salt.
FIG. 5.—The Mutual Solubilities of Ammonium Hexa- and Hepta-fluozirconates.

J. J. Berzelius prepared **potassium pentafluozirconate,** $KF.ZrF_4.H_2O$, by adding a conc. soln. of potassium fluoride to an excess of one of zirconium tetrafluoride ; and, as emphasized by J. C. G. de Marignac, it is decomposed in aq. soln. forming the normal salt. The pentafluozirconate furnishes monoclinic prisms. The aq. soln. does not effervesce when treated with ammonium carbonate. The water of crystallization is lost at 100°. The salt is considered by E. Chauvenet to be **potassium zirconyl dihydropentafluoride,** $KF.ZrOF_2.H_2F_2$. H. L. Wells and H. W. Foote obtained monoclinic crystals of **cæsium pentafluozirconate,** $CsF.ZrF_4.H_2O$, from mixtures containing approximately equimolar proportions of the component salts. The complex salt can be recrystallized from water without change. As just indicated, the salt obtained by the recrystallization of the product of the action of potassium fluoride on an excess of zirconium tetrafluoride is normal **potassium fluozirconate,** K_2ZrF_6. J. C. G. de Marignac obtained the same salt from eq. parts of a soln. of the component salts. J. Missenden made impure potassium fluozirconate by fusing together potassium hydrofluoride and hyacinth, $ZrSiO_4$. The rhombic bipyramidal crystals had the axial ratios $a : b : c$=0·5717 : 1 : 0·6063. D. E. Kerr-Lawson said that the crystals are monoclinic, not rhombic, and have the axial ratios $a : b : c$=0·5731 : 1 : 0·5971, and β=89° 40'. G. von Hevesy gave 1·466 for the maximum, and 1·455 for the minimum refractive index of potassium hexafluozirconate. J. J. Berzelius said that the salt can be heated to redness without loss of weight, and J. C. G. de Marignac that at a red heat, in moist air, hydrogen fluoride is evolved. The salt is sparingly soluble in cold water, and abundantly soluble in hot water. J. Missenden gave for the solubility of potassium fluozirconate expressed in S parts of salt per 100 parts of water :

	10°	20°	30°	40°	50°	60°	70°	80°	90°	100°
S .	1·22	1·55	1·92	2·37	2·94	3·81	5·06	6·90	11·11	23·53

G. von Hevesy and co-workers found the solubility of potassium hexafluozirconate in 0·125N-HF, and 5·89N-HF to be respectively 0·0655 and 0·1297 mol per litre at 20°—*vide* hafnium. On cooling a boiling conc. soln., a mass of acicular crystals is deposited, but less conc. soln. when cooled slowly furnish ill-defined crystals. According to J. J. Berzelius, when a fluozirconate heated with potassium, zirconium is formed. J. C. G. de Marignac found that 100 c.c. of water at 0° dissolve 0·781 grm. of the salt ; 1·41 grms. at 15° ; 1·69 grms. at 10° ; and 25 grms.

at 100°. H. Behrens made rectangular prismatic crystals of normal **rubidium fluozirconate,** Rb_2ZrF_6, by adding rubidium chloride to a soln. of zirconium sulphate mixed with ammonium fluoride and hydrofluoric acid. H. L. Wells and H. W. Foote made normal **caesium fluozirconate,** Cs_2ZrF_6, by mixing a soln. of zirconium tetrafluoride with an excess of one of caesium fluoride. The salt can be recrystallized from water without change ; and it furnishes hexagonal plates with a negative birefringence. According to J. J. Berzelius, if zirconium tetrafluoride be mixed with an excess of potassium fluoride, a salt corresponding with **potassium heptafluozirconate,** $3KF.ZrF_4$, is formed. This salt was also made by H. Behrens. According to J. C. G. de Marignac, the small octahedral crystals belong to the cubic system. G. von Hevesy gave 1·433 for the refractive index. There is no double refraction. The crystals decrepitate when heated ; but if powdered and dried, there is no loss of weight at a red heat. H. Behrens made **rubidium heptafluozirconate,** $3RbF.ZrF_4$, in a similar manner, and obtained strongly refracting, octahedral crystals which were used for the micro-detection of rubidium or zirconium. According to H. L. Wells and H. W. Foote, when a large excess of a soln. of zirconium tetrafluoride is mixed with one of caesium fluoride, small, sparingly soluble crystals were formed with the composition of **caesium tetradecafluotrizirconate,** $2CsF.3ZrF_4.2H_2O$. The crystals acted on polarized light ; and when the aq. soln. was crystallized, the pentafluozirconate was formed. E. Chauvenet represented the salt as $Cs_2ZrF_6.2(ZrOF_2.H_2F_2)$. J. C. G. de Marignac obtained prismatic crystals of **cupric tetradecafluodizirconate,** $3CuF_2.2ZrF_4.16H_2O$, by evaporating a mixed soln. of cupric and zirconium fluorides containing an excess of the latter. The monoclinic crystals have the axial ratios $a:b:c=1·0798:1:1·0337$, and $\beta=91°\ 46'$. The salt crystallizes unchanged from its aq. soln. During the evaporation of the soln., a pale blue crust is formed. This is very sparingly soluble in water, and is supposed to be zirconium fluoride impregnated with the copper salt. If a soln. of the salt be treated with cupric fluoride, monoclinic prisms of **cupric octofluozirconate,** $2CuF_2.ZrF_4.12H_2O$, are formed, having the axial ratios $a:b:c=1·255:1:1·661$, and $\beta=121°\ 17'$. The crystals are said to be isomorphous with the corresponding zinc and nickel salts. The salt dissolves in cold water, and when boiled it deposits a cupric fluoride, and the clear liquid then furnishes crystals of the preceding salt.

J. C. G. de Marignac did not succeed in preparing a well-defined **calcium fluozirconate.** When calcium carbonate was added to an acid soln. of zirconium fluoride, an insoluble precipitate was obtained ; and this was assumed to be a mixture of the fluozirconate and zirconium fluoride. Analogous remarks apply to **strontium fluozirconate** and to **barium fluozirconate.** When barium chloride was added to a soln. of potassium fluozirconate, a precipitate with the composition $3BaF_4.2ZrF_4.2H_2O$, **barium tetradecafluozirconate,** was formed, but whether it is a chemical individual, or a mixture of the normal salt, $BaZrF_6$, with barium fluoride, has not been established.

J. C. G. de Marignac added magnesia to an acid soln. of zirconium fluoride, and obtained a precipitate which proved to be a mixture of magnesium fluoride and **magnesium fluozirconate,** $MgZrF_6.5H_2O$. A soln. of magnesium and zirconium fluorides, on evaporation, deposits small, six-sided, monoclinic plates with curved faces, and these crystals were said to be isomorphous with those of the corresponding salt of manganese. When calcined the salt is decomposed, furnishing a mixture of zirconia and magnesia. J. C. G. de Marignac prepared crystals of **zinc fluozirconate,** $ZnZrF_6.6H_2O$, from a soln. of the component fluorides. The long, hexagonal, prismatic crystals terminate in rhombodedra ; they belong to the triclinic system ; and have the axial ratio $a:c=1:0·5176$. The cleavage along the hexagonal faces is perfect. The crystals are isomorphous with those of the corresponding fluostannate, fluosilicate, chlorostannate, and chloroplatinate. B. Gossner gave 2·258 for the sp. gr. J. C. G. de Marignac added that when roasted, zirconia and zinc oxide are formed, and conc. hydrochloric acid extracts

but imperfectly the zinc oxide from the residue. The corresponding salt of cadmium was not obtained. If a mixed soln. of zinc and zirconium fluorides contains an excess of the former component, crystals of zinc octofluozirconate, $2ZnF_2.ZrF_4.12H_2O$, were formed in monoclinic prisms usually twinned, and with the axial ratios $a : b : c = 1·220 : 1 : 1·644$, and $\beta = 119° 31'$. The crystals are isomorphous with those of the corresponding salt of nickel. The salt is readily soluble in cold water, but is decomposed by boiling water with the deposition of zinc fluoride. The corresponding **cadmium octofluozirconate,** $2CdF_2.ZrF_4.6H_2O$, was obtained in a similar manner in monoclinic prisms with axial ratios $a : b : c = 1·1384 : 1 : 0·838$, and $\beta = 119° 43'$. The crystals are isomorphous with the corresponding salt of manganese. The salt can be recrystallized from water without change. Soln. of cadmium and zirconium fluorides with an excess of the latter component furnish lamellated crystals of **cadmium decafluodizirconate,** $CdF_2.2ZrF_4.6H_2O$.

H. L. Wells and H. W. Foote found that anhydrous **thallous pentafluozirconate,** $TlF.ZrF_4$, is obtained in minute square plates from a mixed soln. of one part of thallous fluoride and 3–4 parts of zirconium tetrafluoride by evaporating until crystals begin to form and then cooling. If the soln. be cooled before precipitation occurs, the hydrated salt, $TlF.ZrF_4.H_2O$, is formed. The salt may be $TlF.ZrOF_2.H_2F_2$. The aq. soln. on crystallization furnishes needle-like crystals of **thallous heptadecafluotrizirconate,** $5TlF.3ZrF_4,H_2O$; and the same salt is produced from a mixture of 1–3·5 parts of thallous fluoride and one of zirconium tetrafluoride ; if four parts of thallous fluoride are employed, the habit of the crystals changes to prisms with hexagonal outlines which are twinned like the hexagonal shaped crystals of aragonite. Both forms give acicular crystals from their aq. soln. This salt may be $TlF.2Tl_2ZrF_6.ZrOF_2.H_2F_2$. It was also found that aq. soln. containing 4–20 parts of thallous fluoride to one of zirconium fluoride furnish brilliant octahedral crystals of **thallous heptafluozirconate,** $3TlF.ZrF_4$. The salt recrystallizes from its aq. soln. without change.

J. C. G. de Marignac added manganese carbonate to a soln. of zirconium tetrafluoride in hydrofluoric acid, and obtained from the liquid monoclinic prisms of **manganese fluozirconate,** $MnZrF_6.5H_2O$, and the axial ratios $a : b : c = 2·090 : 1 : 1·184$, and $\beta = 123° 10'$. The cleavage is imperfect. The crystals sometimes have a tabular habit, and show twinning, and they are isomorphous with the corresponding magnesium salt. The salt is decomposed by sulphuric acid ; and when heated, it furnishes a mixture of zirconia, and manganese oxide. J. C. G. de Marignac also made **manganese octofluozirconate,** $2MnF_2.ZrF_4.6H_2O$, from a soln. of the component salts containing an excess of manganese fluoride. The short thick prisms belong to the monoclinic system and have the axial ratios $a : b : c = 1·3710 : 1 : 0·8362$, and $\beta = 118° 41'$. The cleavage is perfect. The salt dissolves in cold water without decomposition, and the soln. can be boiled without becoming turbid, but if boiling water be poured directly on the crystals, they are decomposed with the separation of manganese fluoride, and the clear liquid, on evaporation, furnishes the normal fluozirconate. J. C. G. de Marignac prepared **nickel fluozirconate,** $NiZrF_6.6H_2O$, by evaporating a mixed soln. of the component salts. The green thick prisms belong to the trigonal system, and have the axial ratio $a : c = 1 : 0·5176$, and are isomorphous with the corresponding fluosilicate and fluostannate, and with zinc fluozirconate. The cleavage is complete. When roasted, zirconia and nickel oxide are formed. If the mixed soln. of the component salts contains hydrofluoric acid and an excess of nickel fluoride, emerald-green prisms of **nickel octofluozirconate,** $2NiF_2.ZrF_4.12H_2O$, are formed. They belong to the monoclinic system, and have the axial ratios $a : b : c = 1·2110 : 1 : 1·6265$, and $\beta = 119° 10'$. The crystals generally show twinning or trilling. The salt dissolves in cold water without change, and if the aq. soln. is boiled, the soln. deposits some nickel fluoride. Mixed hot soln. of nickel and potassium fluozirconates at first deposit needle-like crystals of ordinary potassium fluozirconate ; these are gradually redissolved and pale green prisms of the triple salt, **potassium nickel fluozirconate,**

$K_2Ni(ZrF_6)_2.8H_2O$, appear. The salt is sparingly soluble in water, and is deposited almost quantitatively from a mixture of eq. proportions of soln. of the component salts. The monoclinic crystals have the axial ratios $a : b : c$ $=0.6589 : 1 : 1.1789$, and $\beta=95°\ 40'$. The habit of the crystals is very variable. No water is lost at $100°$, but at a higher temp., hydrogen fluoride is given off.

§ 10. Zirconium Chlorides and Chlorozirconates

O. Ruff and R. Wallstein [1] reduced zirconium tetrachloride by aluminium, magnesium, zinc, mercury, arsenic, and tin, and found that aluminium chloride acts as a stimulant. The product of the reduction at $250°-300°$ is **zirconium trichloride**, $ZrCl_3$, which is a brown solid at ordinary temp., and is converted into **zirconium dichloride**, $ZrCl_2$, and the tetrachloride: $2ZrCl_3=ZrCl_2+ZrCl_4$, above $330°$; and when the dichloride is heated above $600°$, zirconium and zirconium tetrachloride are formed: $2ZrCl_2=Zr+ZrCl_4$. J. J. Berzelius reported that when amorphous zirconium is gently heated in chlorine gas, it takes fire and burns, forming a white substance which does not volatilize. Subsequent investigations showed that the presence of moisture must be carefully excluded, and that **zirconium tetrachloride**, $ZrCl_4$, prepared in this way from thoroughly dried materials is volatile at about $300°$; and in the presence of moisture hydrolysis readily occurs. G. H. Bailey used this mode of preparation; and L. Troost passed chlorine or hydrogen chloride over crystalline zirconium at a red heat. F. Wöhler made zirconium tetrachloride by passing a current of chlorine over a mixture of zirconia and carbon at a red heat. F. Wöhler also used zircon in place of zirconia. D. E. Melliss, C. M. T. du Motay, and R. Hornberger found that it is difficult to separate silicon tetrachloride from the product of this reaction when the raw material contains silica; although, as L. Troost and P. Hautefeuille have shown, when silicon tetrachloride is passed over heated zirconia, silica and zirconium tetrachloride are formed. H. S. Cooper passed chlorine over zirconium carbide at $500°-550°$, and condensed the sublimed tetrachloride at $200°$. L. Burgess obtained the chloride by the action of hydrogen chloride on the product obtained by heating a zirconium ore with carbon. L. Troost observed the formation of zirconium tetrachloride when boron trichloride is passed over heated zirconia; E. F. Smith and H. B. Harris, when phosphorus pentachloride and zirconia are heated in an evacuated glass tube between $150°$ and $190°$; E. Wedekind, and H. Moissan and F. Lengfeld, when zirconium nitride is heated to dark redness in a stream of chlorine; and H. Moissan and F. Lengfeld, L. Renaux, E. Wedekind, and A. Stähler and B. Denk, by heating zirconium carbide to $300°$ in a current of chlorine. E. Chauvenet found that at $400°$, carbonyl chloride reacted with zirconia, forming the tetrachloride. C. Baskerville used this reaction. F. P. Venable and D. H. Jackson said that better results are obtained by using a mixture of carbon monoxide and chlorine at $480°$ with

the former in excess, and at 425°, with the latter in excess.   J. Barlot and E. Chauvenet treated zircon at 1250°–1300° with carbonyl chloride.   E. A. Demarçay obtained zirconium tetrachloride by the action of carbon tetrachloride on zirconia above 400° ; V. Meyer and F. Wilkins said that they did not observe any reaction, but they probably used too small a proportion of carbon tetrachloride. D. Lely and L. Hamburger said that a mixture of carbon tetrachloride and chlorine reacts with zirconia at 800°, and F. P. Venable and J. M. Bell regard this as a most convenient method of making zirconium tetrachloride.   The reaction is quantitative, beginning at about 3C0°, and progressing rapidly at 550°–600°. F. Bourion made zirconium tetrachloride by the action of a mixture of the vap. of chlorine and sulphur chloride on zirconia at a dull red heat.   The contamination with sulphur chloride can be removed by reheating the product in a stream of chlorine.   The dissociation of dried zirconyl chloride, $ZrOCl_2$, at about 110° furnishes zirconium tetrachloride : $2ZrOCl_2 = ZrO_2 + ZrCl_4$.   The method was used by E. Chauvenet.   F. P. Venable and J. M. Bell said that the yield is less than 10 per cent., and that the reaction begins about 300°—D. Lely and L. Hamburger said 600°.   F. P. Venable said that the anhydrous tetrachloride cannot be obtained from aq. soln.

Zirconium tetrachloride forms white crystals which when exposed to moist air give off fumes of hydrogen chloride, produced by the hydrolysis of the salt. Zirconium tetrachloride can be recrystallized from conc. hydrochloric acid, but some hydrolysis occurs at the same time.   The salt sublimes when heated over 300°, forming clear crystals.   The salt hisses when placed in water, and the reaction is energetic, much heat is evolved, and zirconyl chloride passes into soln.   A. Voigt and W. Biltz measured the electrical conductivity of the fused salt.   S. R. Paykull, and R. Hornberger found that the aq. soln. does not form double salts of zirconium tetrachloride with alkali, barium, zinc, or auric chloride.   F. P. Venable and J. M. Bell gave 2·8 for the sp. gr. at room temp.   R. Hermann, and H. St. C. Deville and L. Troost found the vap. density of the tetrachloride at 440°–450° to be 8·15 when the theoretical value for $ZrCl_4$ is 7·73.   A. Voigt and W. Biltz showed that zirconium tetrachloride does not melt without decomposition.   L. Wolter found that dry hydrogen fluoride converts it into zirconium tetrafluoride.   According to W. Biltz and E. Meinecke, zirconium tetrachloride is insoluble in liquid chlorine.   F. P. Venable and R. O. Dietz found that zirconium tetrachloride reacts with hydrogen sulphide, forming a compound which when heated yields the sulphide.   W. Biltz and E. Keunecke observed that no sulphohydrate, $ZrCl_4.nH_2S$, could be prepared. F. P. Venable and R. O. Deitz also showed that zirconium tetrachloride reacts with carbon at a high temp., forming the carbide (q.v.) ; zirconium tetrachloride vap. reacts with methane at 400°, and with acetylene an exothermic reaction sets in at a gentle heat.   According to R. Hornberger, and O. Hinsberg, zirconium tetrachloride dissolves in absolute alcohol with a hissing noise, but A. Rosenheim and P. Frank could not prepare an alcoholate or hydrate from the alcoholic soln. R. Hornberger found that the alcoholic soln. gives off ethyl chloride when heated. If the alcoholic soln. be sat. with hydrogen chloride, complexes of the type $M_2H_2ZrCl_6$ are formed, where M represents pyridine, quinoline, etc.   J. M. Matthews found that zirconium tetrachloride is soluble in ether, and in the ethereal soln. it can form addition compounds when treated with ammonia or organic bases ; while, according to A. Rosenheim and J. Hertzmann, it forms an addition compound with ether, and with benzoic acid, salicylic acid, acetic acid, formic acid, propionic acid, ethyl benzoate, ethyl salicylate, aldehyde, ketone, etc.   W. Peters observed no reaction between zirconium tetrachloride and mercury ethide or phenylide at 200° in evacuated tubes.   G. T. Morgan and A. R. Bowen prepared derivatives by the interaction of β-diacetones with zirconium tetrachloride. E. Chauvenet studied the electrical conductivity of a 0·01N-soln. of zirconium chloride during progressive treatment with an 0·01N-soln. of sodium hydroxide, and also from measurements of the heat developed under similar conditions, and

concluded that the results obtained point to the existence of the radicle (ZrO) in zirconium compounds.

J. Persoz found that zirconium tetrachloride rapidly absorbs ammonia at ordinary temp. S. R. Paykull obtained what he regarded as **zirconium tetramminotetrachloride,** $ZrCl_4.4NH_3$, in this way. According to J. M. Matthews, if the tetrachloride is cold, *zirconium diamminotetrachloride*, $ZrCl_4.2NH_3$, is formed, and if heated, the tetrammine. The diammine was probably not properly sat. with ammonia. On the other hand, A. Stähler and B. Denk obtained **zirconium octamminotetrachloride,** $ZrCl_4.8NH_3$, as a loose, white, hygroscopic powder by the action of ammonia on the anhydrous tetrachloride at 16°, until the weight was constant; and at 232°, he obtained **zirconium triamminotetrachloride,** $ZrCl_4.3NH_3$. J. M. Matthews prepared the octammine by the action of dry ammonia on a soln. of zirconium tetrachloride in ether. When the octammine is heated, ammonia is first evolved; then ammonium chloride; and finally zirconium nitride remains. The octammine is very hygroscopic in air, and loses ammonia; it reacts with water, forming ammonium chloride, and precipitating zirconium hydroxide. F. P. Venable and R. O. Deitz found that the product of the action of ammonia on the tetrachloride furnishes the nitride when heated. J. M. Matthews obtained compounds of zirconium chloride with 4 mols. of methylamine, ethylamine, propylamine, aniline, toluidine, and β-naphthylamine. No combination occurred with nitrosyl chloride, nitrogen peroxide, ·sulphur monochloride, phosphorus chlorides, cyanogen, hydrogen cyanide, cyanogen chloride, acetonitrile, benzonitrile, diphenylamine, and acid amides. C. Vincent found that the organic amines produce with aq. soln. of zirconium chlorides precipitates similar to those obtained with ammonia. F. P. Venable and R. O. Deitz found that zirconium tetrachloride reacts with phosphine, forming a compound which, when heated, yields the phosphide. S. R. Paykull, and E. F. Smith and H. B. Harris observed a reaction between zirconium tetrachloride and phosphorus pentachloride, forming **zirconium phosphorus tridecachloride,** $2ZrCl_4.PCl_5$, as a white mass melting at 240°, and boiling at 325°; J. H. de Boer and A. E. van Arkel gave 164·5° for the m.p., and 416° for the b.p. They also prepared **zirconium phosphorus oxyhenachloride,** $2ZrCl_4.POCl_3$, boiling at 363°–364°. O. Ruff observed that zirconium tetrachloride united with sulphur chloride.

M. Weibull obtained what he regarded as **potassium chlorozirconate**—possibly K_2ZrCl_6—by passing the vap. of zirconium tetrachloride over fused potassium chloride; and S. R. Paykull prepared **sodium chlorozirconate,** Na_2ZrCl_6, in an analogous manner. R. Ruer observed that in the electrolysis of a mixed soln. of zirconium and sodium chlorides, some zirconium passed to the anode compartment.

S. R. Paykull said that the tetrachloride cannot exist in aq. soln., and as emphasized by G. H. Bailey, when zirconium chloride is exposed to moist air or dissolved in water, it is hydrolyzed, and zirconyl chloride, $ZrOCl_2$, is formed. Aq. soln. of zirconium chloride thus have an acidic reaction. R. Ruer showed that the hydrolysis progresses slowly at ordinary temp., and it is influenced by both temp. and conc. Working with a $\frac{1}{4}N$-soln. of zirconyl chloride, $ZrOCl_2.8H_2O$, at 18°, R. Ruer found that, owing to the increasing conc. of the hydrochloric acid produced by the hydrolysis, the sp. conductivity increases at the rate of about 67×10^{-5} mho per min. during the first hour, and for the next 168 hrs. it is almost stationary:

Hours	0·083	0·169	1	5	24	48	72	168
Mho $\times 10^5$	1469	1556	1867	1980	2024	2071	2104	2107

After the lapse of 168 hrs., the soln. was boiled, and the sp. conductivity rose to 2777×10^{-5} mho, indicating the formation of a more basic chloride; 72 hrs. later, the conductivity fell to 2722×10^{-5} mho, indicating a reversal of the reaction or the escape of some free acid. The hydrolysis of aq. soln. of zirconyl chloride of

different conc., at $0°$ and $20°$, was measured by F. P. Venable and D. H. Jackson by the sp. conductivity method, and by precipitation with iodic acid. The results were analogous. When ionized in soln., the zirconyl radicle acts as cation. In the presence of sodium chloride, R. Ruer found some of the zirconium passed to the anode compartment. There are four possible stages in the hydrolysis of zirconium tetrachloride, namely $ZrCl_4 \rightarrow Zr(OH)Cl_3 \rightarrow Zr(OH)_2Cl_2 \rightarrow Zr(OH)_3Cl \rightarrow Zr(OH)_4$. E. Chauvenet tried to obtain indications of the different stages by the progressive addition of $0.01N$-NaOH to a $0.01N$-soln. of zirconium chloride at $309°$, and measuring the changes in the electrical conductivity. The results furnished a curve with two breaks corresponding with $ZrOCl_2$ and $Zr_2O_3Cl_2$.

J. J. Berzelius showed that when the aq. soln. of zirconium chloride, or the soln. of zirconium hydroxide in hydrochloric acid is conc. by evaporation, small, colourless, needle-like crystals with a bitter astringent taste are formed, and the mother-liquid has an excess of hydrochloric acid. The crystals represent normal basic salt, which E. Chauvenet showed to be **octohydrated zirconyl chloride,** $ZrOCl_2.8H_2O$, whether it be crystallized from water or from hydrochloric acid. This compound was also obtained by R. Hermann, and S. R. Paykull. According to F. P. Venable, if the soln. is made strongly acid, the crystallization is almost quantitative because the octohydrate is only slightly soluble in conc. hydrochloric acid. The addition of water precipitates this salt from an acid soln., and conc. hydrochloric acid precipitates it from an aq. soln. The precipitates are gradually redissolved on standing in their mother-liquids. The re-solution of the precipitate depends on the acidic conc. of the mother-liquid. J. M. Matthews obtained this chloride of a high degree of purity by adding water to an ethereal soln. of zirconium tetrachloride; and O. Kulka, by evaporating a soln. of zirconium tetrachloride in alcoholic hydrochloric acid. The determination of the water is difficult because at $70°$ hydrochloric acid as well as water is given off, and O. Kulka, and R. Hermann represented the composition of the crystals $ZrOCl_2.9H_2O$, or $Zr(OH)_2Cl_2.8H_2O$. The crystals are soluble in hot conc. hydrochloric acid and are re-deposited on cooling. This furnishes a means of purifying the salt; and R. Ruer recommended the formation of this salt as a means of detecting zirconium :

The precipitate obtained by adding aq. ammonia is separated from the filter-paper and dissolved in hydrochloric acid. The soln. is evaporated to dryness on the water-bath and then dissolved in a little water. Conc. hydrochloric acid is added drop by drop so as to obtain a precipitate of the oxychloride ; this precipitate goes into soln. on warming the liquid, and on cooling separates again in crystals which have a characteristic appearance (thin prisms) under the microscope.

According to M. Weibull, R. Ruer, and K. Haushofer, the crystals belong to the tetragonal system, and the axial ratio is $a : c = 1 : 0.3182$. G. von Hevesy gave $\omega = 1.563$ and $\epsilon = 1.552$ for the refractive indices of the needle-like crystals of the octohydrate. The crystals deliquesce in moist air, and they may be dried in air without loss of hydrochloric acid ; in dry air, the crystals effloresce and, according to E. Chauvenet, the loss of water ceases when the composition becomes that of the *hexahydrate*, $ZrOCl_2.6H_2O$. R. Paykull said that the hydrate is $ZrOCl_2.6\frac{1}{2}H_2O$, and is produced by adding hydrochloric acid to a soln. of normal zirconyl chloride. F. P. Venable and C. Baskerville, however, showed that the composition is that of the hexahydrate. H. Lange gave $ZrOCl_2.5\frac{1}{2}H_2O$, and D. E. Melliss, $ZrOCl_2.4\frac{1}{2}H_2O$. H. Lange also claimed to have made the *tetrahydrate*, $ZrOCl_2.4H_2O$, by heating the normal hydrate. At $50°$, J. J. Berzelius said that the crystals become opaque and lose half their acid together with their water of crystallization ; but E. Chauvenet said that in a stream of dry air at $50°$, the limit of the desiccation is the *hemiheptahydrate*, $ZrOCl_2.3\frac{1}{2}H_2O$. J. Missenden found that the octohydrate loses 80 per cent. of its water below or at $36°$, and all at $57°$. F. P. Venable showed that if dried at $100°-125°$ in a stream of hydrogen chloride, the *trihydrate*, $ZrOCl_2.3H_2O$, is formed ; and if the temp. be raised to $150°$, E. Chauvenet said that the *dihydrate*, $ZrOCl_2.2H_2O$, is formed ; and from his thermochemical data,

he limited the hydrates of this compound to the octo-, hexa-, hemihepta-, and the di-hydrate. According to F. P. Venable, the last of the water of hydration is lost at 180°–210°. L. Troost and P. Hautefeuille made anhydrous zirconyl chloride, $ZrOCl_2.ZrCl_4$, or Zr_2OCl_6, by heating to redness zirconium tetrachloride in a stream of oxygen. E. Chauvenet said that this statement is based on an error. If the oxygen is not thoroughly dried, a small proportion of the zirconium tetrachloride is hydrolyzed, and the zirconyl chloride at 300° dissociates into zirconium tetrachloride and zirconia, and small amounts of zirconia may be entrained in the zirconium tetrachloride. Hence the alleged volatile zirconyl chloride is really a mixture of the tetrachloride and dioxide. F. P. Venable and D. H. Jackson found that when zirconium tetrachloride or any of the basic chlorides is heated to 1000° for a long time, a small portion of the chlorine is retained. According to J. J. Berzelius, zirconyl chloride is soluble in water and alcohol; and the dil. aq. soln. does not become turbid when boiled. J. J. Berzelius, R. Hermann, R. Ruer, and F. P. Venable and C. Baskerville showed that the salt is sparingly soluble in cold hydrochloric acid; and that the solubility is less the more conc. the acid. A comparison of the solubility of the hafnium and zirconium oxychlorides in hydrochloric acid is shown in Fig. 4, in the chapter on hafnium.

E. Wedekind said that when heated to 100°–110°, zirconyl chloride becomes less soluble in water. E. Linnemann, R. Hermann, and, as just indicated, J. J. Berzelius observed the loss of acid which occurs when the soln. of zirconyl chloride is evaporated to dryness. The progressive hydrolysis of the aq. soln. of zirconyl chloride has just been discussed. R. Ruer showed that the behaviour of aq. soln. of zirconyl chloride towards oxalic acid and ammonium oxalate in the presence of acids and sulphates also indicated that a hydrolytic change had occurred. When an aq. soln. of zirconium oxychloride is boiled for a short time, the hydrolysis undergone and the alteration of the analytical behaviour of the soln. are marked. Such soln., for instance, form precipitates with sodium sulphate and ammonium sulphate respectively, which are redissolved by an excess of precipitant; the precipitate, formed on the addition of dil. sulphuric acid, is slowly dissolved by an excess of the latter. C. W. G. Nylander also obtained products with a different composition when prepared in different ways. According to H. Endemann, if ether be added to a warm soln. of zirconyl chloride, a crystalline precipitate is formed with the composition $Zr_2O_3Cl_2.nH_2O$. It is soluble in water and separates as an amorphous powder on evaporation, and it passes into normal zirconyl chloride when warmed with hydrochloric acid. R. Ruer said that the precipitate from the ethereal soln. is amorphous. A. Rosenheim and P. Frank gave $Zr_2O_3Cl_2.5H_2O$ for the air-dried substance; and E. Chauvenet represented it as *trihydrated zirconium trioxydichloride*, $Zr_2O_3Cl_2.3H_2O$, hydrated **zirconium trioxydichloride,** or $ZrOCl_2.ZrO_2.3H_2O$:

$$\begin{matrix} O{=}Zr{<}\begin{matrix}Cl\\O\end{matrix} \\ O{=}Zr{<}\begin{matrix}\\Cl\end{matrix}\end{matrix} +3H_2O$$
It can also be regarded as $ZrO(OH)Cl.H_2O$. E. Chauvenet made the anhydrous salt by heating dihydrated zirconyl chloride to 230° in an atm. of hydrogen chloride. At 300°, the anhydrous salt dissociates into zirconia and zirconium tetrachloride.

More advanced stages in the hydrolysis were reported by H. Endemann, who said that when ether is added to a cold alcoholic soln. of zirconyl chloride, a gelatinous precipitate is formed which is soluble in water, and when dried has the composition $8ZrO_2.7HCl$. R. T. Glazebrook and co-workers dissolved zirconium hydroxide in hydrochloric acid, and after concentrating the soln., claimed that a crystalline precipitate of a mixture of octohydrated zirconyl chloride, $ZrOCl_2.8H_2O$, and another basic salt, *zirconium octoxytetrachloride*, $Zr_5O_8Cl_4.22H_2O$, is formed. On recrystallization from hydrochloric acid, sp. gr. 1·08, the latter

is alone. obtained.   According to E. H. Rodd, this salt is a tetrachlorozirconyl zirconate :

$$\begin{array}{c} \text{Cl.ZrO.O} \\ \text{Cl.ZrO.O} \end{array} > \text{Zr} < \begin{array}{c} \text{O.ZrO.Cl} \\ \text{O.ZrO.Cl} \end{array} \qquad \text{or} \qquad \begin{array}{c} \text{Cl}_2 = \text{Zr.O.ZrO.O.ZrO.O.Zr} = \text{Cl}_2 \\ \text{O} \text{------} \text{O} \text{------} \text{O} \end{array}$$

The aq. soln. of this chloride resembles freshly prepared soln. of zirconyl chloride in giving a precipitate with oxalic acid or ammonium oxalate which is soluble in an excess of the precipitant ; it behaves similarly with ammonium carbonate ; and gives a gelatinous precipitate with hydrogen dioxide.   Unlike the soln. of zirconyl chloride, however, when treated with sulphates or sulphuric acid it furnishes the corresponding sulphato-salt by double decomposition.   The soln. of zirconyl chloride which has been boiled resembles in many ways a soln. of tetrachlorozirconyl zirconate.   Both soln. give a white precipitate with sulphuric acid ; an unboiled soln. of zirconyl chloride does not give such a precipitate ; the general properties of the hydroxides precipitated with ammonia are different in boiled and unboiled soln. of zirconyl chloride.   The hydroxide from the unboiled soln. does not dissolve in a soln. of zirconyl chloride, while that from the boiled soln. is readily soluble on warming.   A soln. of tetrachlorozirconyl zirconate in one of zirconyl chloride deposits crystals of both salts on evaporation.   Attempts to obtain tetrachlorozirconyl zirconate from a boiled soln. of zirconyl chloride were not successful.

R. Ruer dialyzed a 3 per cent. aq. soln. of zirconyl chloride but could not get a ratio higher than $ZrO_2 : Cl = 50 : 1$.   When silver nitrate is added to the soln. a faint opalescence appears and the soln. becomes gelatinous after a few minutes. When nitric acid is added along with silver nitrate, a slight turbidity appears, which becomes more marked when the soln. is boiled, until finally all the silver is deposited as chloride.   From this and from the analogous behaviour of ferric hydroxide, the conclusion is drawn that the colloidal soln. in question contained chlorine in the form of hydrochloric acid or metallic chloride or oxychloride, dissociation having occurred partially.   The behaviour of the soln. towards silver nitrate is attributed to a specific action of the colloidal hydroxide by which the silver chloride formed is retained in soln. in the colloidal form.   R. Ruer evaporated a dil. soln. of zirconyl chloride to a small vol. and diluted and evaporated the product three or four times so as to drive off most of the hydrochloric acid liberated by hydrolysis.   The finely divided precipitate which settled out was washed with water and hydrochloric acid by centrifugal action.   The precipitate was dried over sulphuric acid and potassium hydroxide.   It was only partly dehydrated at 130°, and it lost no hydrochloric acid at that temp.   The analyses correspond with $(ZrO)_5(OH)Cl.nH_2O$.   R. Ruer called it *metazirconic chloride*, but there is no satisfactory evidence of chemical individuality.   This substance before drying is soluble in water, and when the soln. is hydrolyzed, the product has less than 1 per cent. of chlorine, and may be regarded as a zirconium hydroxide, although R. Ruer called it *metazirconic acid*.   It is difficult to transform metazirconic chloride into zirconyl chloride by the action of hydrochloric acid ; for, after boiling 5 grms. with 500 c.c. of conc. acid for 3 hrs., only 20 per cent. was changed ; about 30 hrs. were needed for the complete conversion of metazirconic chloride into normal zirconyl chloride.   M. Adolf and W. Pauli studied the ionization of aq. soln. of zirconium oxychloride soln.

§ 11. Zirconium Bromides and Iodides

D. E. Melliss [1] prepared anhydrous **zirconium tetrabromide**, $ZrBr_4$, by passing carbon dioxide sat. with bromine vapour over an intimate mixture of zirconia and sugar charcoal. G. H. Bailey obtained the same salt by heating zirconium in the vap. of bromine. A. Stähler and B. Denk passed bromine vap. and carbon dioxide over zirconium carbide at a red heat; and E. Wedekind observed that bromine reacts with heated zirconium nitride *unter Feuererscheinung* producing the tetrabromide. According to D. E. Melliss, zirconium tetrabromide is a white microcrystalline powder which can be volatilized without decomposition at the heat of a Bunsen's burner. The salt is very hygroscopic. It is not reduced when heated in a current of hydrogen. When treated with water, it forms hydrogen bromide, bromine, and a soln. of zirconyl bromide. According to A. Rosenheim and P. Frank, it dissolves in alcohol with the formation of hydrogen bromide. It is soluble in ether. A. Stähler and B. Denk prepared **zirconium decammino-tetrabromide**, $ZrBr_4.10NH_3$, by saturating zirconium tetrabromide with dry ammonia at ordinary temp.; this occupies about 12 hrs. The white powder is very hygroscopic, and readily gives off ammonia; it changes very little, however, if dried air be passed over it for a short time. It is decomposed by water making a hissing noise. If dried ammonia be passed over warmed zirconium tetrabromide, J. M. Matthews found that white **zirconium tetramminotetrabromide**, $ZrBr_4.4NH_3$, is formed. When heated, either ammine furnishes the nitride, and if further heated in hydrogen, zirconium metal is produced. A. Rosenheim and P. Frank prepared addition compounds with ethylamine, aniline, and pyridine; and by adding pyridine and quinoline to a soln. of hydrogen bromide in alcohol sat. with zirconium hydroxide, they obtained the **bromozirconates**, $(C_5H_5NH)_2ZrBr_6$, and $(C_9H_7NH)_2ZrBr_6$, respectively.

J. B. Berthemot dissolved zirconium hydroxide in hydrobromic acid, allowed the soln. to crystallize, and obtained granular crystals of an astringent taste. It

is difficult to dry the salt without decomposition, since D. E. Melliss showed that it loses water and hydrogen bromide at 100°, and F. P. Venable and C. Baskerville found these losses occurred in a current of dry air or over a desiccating agent. The composition of the salt, according to M. Weibull, and O. Kulka, approximates to **octohydrated zirconyl bromide,** $ZrOBr_2.8H_2O$; D. E. Melliss' analysis makes the salt approximate the heptahydrate ; and F. P. Venable and C. Baskerville obtained it with 13–14H_2O. D. E. Melliss made it by evaporating an aq. soln. of the tetrabromide ; and O. Kulka by evaporating in vacuo a soln. of zirconium hydroxide in alcoholic hydrobromic acid. D. E. Melliss obtained acicular crystals which, according to M. Weibull, are optically uniaxial, tetragonal, and isomorphous with the corresponding chloride. F. P. Venable and C. Baskerville found the crystals to be more hygroscopic than those of zirconyl chloride, and to decompose on exposure to moist air. The salt is soluble in hot conc. hydrobromic acid, and is re-deposited on cooling. When the salt is dried at 100°–120° in a stream of hydrogen bromide, a hard crystalline mass is obtained with the composition of the *tetrahydrate,* $ZrOBr_2.4H_2O$, or $Zr(OH)_2Br_2.3H_2O$, and which is readily soluble in water. E. Chauvenet could find no evidence of the hydrates reported by A. Knop, and S. R. Paykull, for when the octohydrate is dried in a current of dry air or in vacuo, it furnishes a *hemiheptahydrate,* $ZrOBr_2.3\frac{1}{2}H_2O$, which is stable up to 60°–70°. Above this temp. it loses both water and hydrogen bromide, forming the basic salt $Zr_2O_3Br_2$, **zirconium trioxydibromide.** This basic bromide is slowly deposited from a $0.01N$-soln. of zirconyl bromide when allowed to stand for a long time ; and on adding ether to an alcoholic soln. of zirconyl bromide, **dodecahydrated zirconium trioxydibromide,** $Zr_2O_3Br_2.12H_2O$, is deposited. These basic salts are converted into zirconium tetrabromide when heated to redness in a current of hydrogen bromide.

F. P. Venable and C. Baskerville boiled for a long time a sat. soln. of zirconium hydroxide in conc. hydrobromic acid, and, when the soln. was evaporated on a water-bath, it deposited white, prismatic crystals of a basic salt, $ZrO(OH)_2.ZrOBr_2.4H_2O$, or **zirconyl hydroxybromide,** $ZrO(OH)Br.2H_2O$, or *zirconium trihydroxybromide,* $Zr(OH)_3Br.H_2O$. The soln. contained some gelatinous zirconium hydroxide, and, on further evaporation, furnished a crop of acicular crystals which on analysis had rather less water of hydration. The colloidal zirconia could be separated from the soln. by dialysis. M. Weibull reported a similar basic salt.

D. E. Melliss, and O. Hinsberg did not succeed in preparing **zirconium tetra-iodide,** ZrI_4, by heating a mixture of zirconia and carbon in a current of iodine vap. carried along by carbon dioxide ; or by heating a mixture of zirconium tetra-bromide and potassium iodide in a stream of carbon dioxide. G. H. Bailey, and L. M. Dennis and A. E. Spencer also achieved no success by heating zirconium to dull redness in a current of iodine vapour and hydrogen. The latter, however, obtained the tetraiodide by passing hydrogen iodide over zirconium. They said :

As the temp. of the tube containing the zirconium is gradually increased, an amorphous, white sublimate, probably of ferrous iodide obtained from traces of iron in the metal, is first formed, and finally, at a bright red-heat, a white, crystalline sublimate was deposited immediately beyond the red-hot portion of the tube. After cooling in a current of hydrogen, the zirconium was found to have changed from black to greyish-white, but contained very little iodine.

A. Stähler and B. Denk prepared the tetraiodide by heating zirconium or its carbide in a current of dried hydrogen iodide. A vigorous reaction sets in at 340° in the case of the metal, and at 490° in the case of the carbide. Unlike L. M. Dennis and A. E. Spencer, A. Stähler and B. Denk found that the sublimate is brown not white. The hydrogen iodide was driven from the apparatus by a current of hydrogen, and the sublimate digested with benzene at 100° in a sealed tube to remove the free iodine. The mixture was filtered in an atm. of hydrogen, washed with benzene and dried. L. M. Dennis and A. E. Spencer seem to have

gone wrong in their description of zirconium tetraiodide, and the following observations were reported by A. Stähler and B. Denk. Zirconium tetraiodide is a yellow, microcrystalline powder which fumes in air, and dissolves in water and acids with a vigorous reaction. L. M. Dennis and A. E. Spencer said the iodide is unchanged by boiling it with water. The tetraiodide reacts energetically with alcohol, forming ethyl iodide and zirconium hydroxide; it is slightly soluble in benzene, and carbon disulphide; and it readily dissolves in dry ether, forming an addition product, $ZrI_4.4(C_2H_5)_2O$.

A. Stähler and B. Denk attempted to remove the iodine from the unpurified tetraiodide by heating in vacuo, or in a stream of carbon dioxide. The reddish-brown product so obtained when heated over 300° gave a dark brown vap. which condensed to a reddish-brown powder, with a constant composition, and in *vielleicht eine molekulare Verbindung*, **zirconium hexaiodide**, $ZrI_4.I_2$. The tetra-iodide forms addition products with ammonia, ethylamine, and propylamine. When a stream of dry ammonia is passed over crystals of the tetraiodide, below 22°, until the salt is saturated, **zirconium octamminotetraiodide**, $ZrI_4.8NH_3$, is formed. This compound was also obtained by digesting the tetraiodide with liquid ammonia at 60°, and evaporating off the excess of liquid; and by passing dry ammonia into an ethereal soln. of the tetraiodide. A. Stähler and B. Denk raised the question if this product is really a mixture of ammonium iodide and zirconium tetramide, $ZrI_4.8NH_3 = Zr(NH_2)_4 + 4NH_4I$, because, like boron hexam-minotrichloride, and silicon hexamminotetrachloride, ammonium halide is removed by washing with liquid ammonia. On the other hand, when the octammine is heated, there is a gradual loss of ammonia on raising the temp. so that at 100°, the composition corresponds with **zirconium heptamminotetraiodide**, $ZrI_4.7NH_3$; at 150°, with **zirconium hexamminotetraiodide**, $ZrI_4.6NH_3$; and up to 200°, with **zirconium tetramminotetraiodide**, $ZrI_4.4NH_3$. Only at 200° is there any sign of ammonium iodide, corresponding with the decomposition of the salt to the nitride, etc., as in the analogous case of the ammines of zirconium tetrachloride and tetra-bromide. It may be that those ammines are decomposed by liquid ammonia.

According to D. E. Melliss, an oxyiodide is not formed when zirconium hydroxide is dissolved in hydriodic acid; and F. P. Venable and co-workers found that zirconium hydroxide, precipitated from hot soln., is scarcely attacked by this acid, and even the hydroxide precipitated from cold soln. is only sparingly dissolved. The best results were obtained by passing hydrogen iodide into water in which the hydroxide was suspended. The evaporation of the soln. furnishes a hornlike mass coloured with iodine; if the evaporation be conducted in an atm. of carbon dioxide to limit the decomposition of the iodide, crystals of **octohydrated zirconyl iodide**, $ZrOI_2.8H_2O$, were obtained. The same salt was obtained in a similar manner by M. Weibull, and he removed the free iodine by washing with chloroform or carbon disulphide. A. Stähler and B. Denk prepared it by evaporating an aq. soln. of zirconium tetraiodide, and washing out the free iodine with ether. The salt so obtained appears in colourless needle-like crystals, which are very hygroscopic; soluble in water or alcohol; and decomposed by heat into zirconia and hydrogen iodide. O. Hinsberg prepared the basic salt $ZrO(OH)_2.ZrOI_2.5H_2O$, or **zirconyl hydroxyiodide**, $ZrO(OH)I.2\frac{1}{2}H_2O$, or *zirconium trihydroxyiodide*, $Zr(OH)_3I.1\frac{1}{2}H_2O$, by the double decomposition of soln. of barium iodide and zirconyl sulphate; evaporating the filtered soln. over conc. sulphuric acid; and washing out the free iodine with carbon disulphide. The amorphous, colourless powder decomposes in air and acquires a brown colour from the liberated iodine. It is soluble in water.

§ 12. Zirconium Sulphides and Sulphates

Our knowledge of zirconium sulphide is not in a satisfactory state. J. J. Berzelius [1] heated zirconium with sulphur in an evacuated vessel and observed that combination occurred without the emission of light or heat; when the two elements were heated in an atm. of hydrogen, there appeared a slight flame. The product must have been very impure because the zirconium then available was itself very crude. O. Hauser repeated J. J. Berzelius' experiment also with an impure zirconium. S. R. Paykull obtained an impure sulphide by subliming zirconium tetrachloride in an atm. of hydrogen sulphide. Oxygen was not entirely excluded, and the product was contaminated with oxide or oxysulphide. From analogy with other sulphides, it is inferred that **zirconium sulphide,** ZrS_2, was formed. H. Moissan and F. Lengfeld obtained a little sulphide by the action of sulphur vap. on zirconium carbide at a dull red heat. E. Frémy made an attempt to prepare the sulphide by heating zirconia in an atm. of carbon disulphide. He obtained steel-grey acicular crystals. F. P. Venable and R. O. Dietz obtained the sulphide by the action of hydrogen sulphide on zirconium tetrachloride; and A. E. van Arkel and J. H. de Boer, by passing the vapours of the tetrachloride and sulphur over a heated tungsten filament. A. L. Feild found zirconium sulphide is present in zirconium steels containing 0·07 to 0·32 per cent. of sulphur, and it appears as grey inclusions when the polished surface is etched. It is soluble in hydrochloric acid (1 : 1).

J. J. Berzelius' sulphide was a cinnamon-brown powder which did not acquire a polish under the burnishing tool. A. E. van Arkel found that the crystals belong to the rhombohedral (hexagonal) system with axial ratio $a : c = 1 : 1·59$; and the edge of the hexagon 3·68 A. S. R. Paykull said that the sulphide is stable in air and water, and burns when heated, forming sulphur dioxide. E. Frémy, and S. R. Paykull said that the sulphide is not decomposed by ordinary acids excepting nitric acid, which oxidized it readily with the separation of sulphur. J.J. Berzelius found that the sulphide is decomposed by hydrofluoric acid with the evolution of hydrogen sulphide; and that it is also attacked by aqua regia. S. R. Paykull heated the sulphide in chlorine and obtained zirconium tetrachloride and sulphur chloride. According to A. L. Feild, the normal sulphide, ZrS_2, is soluble in hydrochloric acid (1 : 1), but if more zirconium than corresponds with this ratio is present in the steel, the sulphur is not evolved as hydrogen sulphide upon treatment with the acid, and it is suggested that the excess zirconium is partitioned between the metal and the normal disulphide, the latter forming possibly an insoluble zirconium-zirconium sulphide solid soln., the proportion of sulphur rendered insoluble being 10 per cent. of the zirconium in excess of that required to form the normal disulphide. J. J. Berzelius showed that when zirconium sulphide is fused with potassium hydroxide, zirconia and potassium sulphide are formed. O. Hauser dried the sulphate at 380°–400°, and heated the product at a dull red heat in a current of hydrogen sulphide, and cooled it in the same gas. If removed from the tube before it is quite cold, the product ignites spontaneously in air. Analyses of the light-yellow powder correspond with **zirconyl sulphide,** ZrOS. The sp. gr. is 4·87.

Dried zirconia reacts with sulphuric acid very slowly, and ignited zirconia is scarcely attacked by that acid. J. J. Berzelius [2] prepared normal **zirconium**

sulphate, $Zr(SO_4)_2$, by dissolving zirconia or zirconium hydroxide in an excess of conc. sulphuric acid; evaporating the soln. to dryness; and heating the residue for 15 mins. just below a red heat. According to G. H. Bailey, O. Hauser, F. P. Venable, and M. Weibull, the temp. for driving off the excess of acid should not exceed 350°–400°, or some of the combined acid will be expelled. O. Hauser said that only traces of acid are lost after heating the sulphate for 8 to 10 hrs. at 380°. If a gas-flame is used for the heating, the product must be protected from the water formed in the combustion of the gas, or the sulphate will be partly hydrolyzed. According to J. J. Berzelius, the sulphates prepared by M. H. Klaproth, and L. N. Vauquelin were contaminated with the potassium salt. J. J. Berzelius obtained a gummy mass by the evaporation of an aq. soln. of zirconium sulphate, but if free sulphuric acid be present, crystals of the hydrated salt are formed. These can be washed free from adherent acid by means of alcohol. C. W. G. Nylander's analysis of the hydrate washed with alcohol, and dried by confining it for a short time over conc. sulphuric acid, gave $Zr(SO_4)_2.5H_2O$; but analyses by S. R. Paykull, M. Weibull, and O. Kulka showed that the salt is **tetrahydrated zirconium sulphate,** $Zr(SO_4)_2.4H_2O$. O. Kulka recommended the following process for making the tetrahydrate:

Dissolve zirconia in conc. sulphuric acid over the naked flame, and drive off only a part of the excess acid. Pour the cold, white mush into water. Much heat is developed and the sulphate is dissolved. The clear soln. is then evaporated on a water-bath until a crystalline crust appears on the surface of the liquid. On cooling, crystals of the salt are formed. These are separated from the mother-liquid by suction, and washed with alcohol so as to remove the tenaciously adsorbed acid. The crystals are then dried in air. The salt can be recrystallized from sulphuric acid, but not from water alone, because a basic sulphate would then be formed.

According to M. Weibull, the tetrahydrate furnishes hexagonal plates belonging to the rhombic system, and having the axial ratios $a : b : c = 0.6826 : 1 : 1.3350$. L. Fernandes found that the salt is completely miscible with cerous and uranium sulphates. According to S. R. Paykull, the tetrahydrate loses 3 mols of water at 100°, E. Chauvenet said 120°, and that **monohydrated zirconium sulphate,** $Zr(SO_4)_2.H_2O$, is formed. According to S. R. Paykull, the fourth mol is given off at about 380° below the temp. of decomposition. G. H. Bailey said the salt is stable at 400°; O. Hauser, at 380°. At a higher temp., sulphur trioxide is driven off; but even after heating for some time at 900°–1000°, the last traces of sulphur trioxide are not expelled, and G. H. Bailey said that re-igniting the product mixed with ammonium carbonate will remove the last traces of sulphur dioxide, but the process requires care since some zirconia may be lost by this procedure, being presumably carried away mechanically by the escaping vap. when the normal sulphate is heated in steam at 200°–300°, O. Hauser showed that a basic sulphate, $2ZrO.SO_3$, is formed. According to L. Pissarjewsky, the heat of formation of normal zirconium sulphate from zirconium hydroxide and sulphuric acid is 11·67 cals.; and the heat of reaction with an excess of sulphuric acid is —0·685 cal. According to J. J. Berzelius, the anhydrous salt dissolves slowly but completely in cold water and rapidly in hot water. O. Hauser showed that 100 grms. of the aq. soln. at 39·5° contain 59·3 grms. of the tetrahydrate; and O. Kulka, that 100 grms. of soln. at 18° contain 52·5 grms. of the tetrahydrate. As in the case of the normal chloride, the normal sulphate is readily hydrolyzed in aq. soln. imparting to the liquid a strong acid reaction. The extent of the hydrolysis depends upon the conc., the temp., and the age of the soln. Thus, R. Ruer and M. Levin found the sp. electrical conductivity of a 1·75 per cent. aq. soln. at 18°, after the lapse of one hour, to be 0·03105 mho; and after 20 hrs., 0·03186 mho; when the soln. was boiled the conductivity rose to 0·03418 mho; and 24 and 72 hrs. later the conductivity was 0·03432 mho. F. P. Venable and D. H. Jackson extended these observations working at 0° and 20° with soln. containing 2·026, 20·26, and 40·52 grms. of $ZrOSO_4$ per litre. According to H. Rose, very dil. soln. of zirconium sulphate become

turbid when boiled, owing to the separation of the hydroxide or a basic sulphate, and the soln. becomes clear again as the water is expelled by evaporation.

R. Ruer showed that a soln. of normal zirconium sulphate does not give the characteristic reactions exhibited by the chloride or nitrate when treated with oxalic acid or ammonium oxalate; nor do these reactions occur with soln. of zirconyl chloride to which ammonium or radium sulphate has been added. It is therefore inferred that in aq. soln. zirconium sulphate is constitutionally different from the chloride or nitrate. He suggested that in aq. soln. zirconium sulphate behaves as if it were **zirconyl hydrosulphate,** $ZrOSO_4.H_2SO_4$, or $ZrO(HSO_4)_2$, which, owing to the passage of the zirconium to the anode compartment during electrolysis, and to its forming characteristic potassium, sodium and ammonium salts, is considered to be *eine zweibasische Zirkonschwefelsäure,* **hydrodisulphato-zirconylic acid,** $H_2[ZrO(SO_4)_2]$, or $(HSO_4)_2Zr:O$. On this assumption, it is highly probable that normal zirconium sulphate can exist only in the absence of water, and that the so-called tetrahydrate is really **trihydrated zirconyl hydro-sulphate,** $H_2ZrO(SO_4)_2.3H_2O$. This is confirmed by the ease with which the supposed tetrahydrate loses 3 mols of water and the tenacity with which it retains the fourth mol—*vide supra*—which shows that the molecule is dissociated and water is reformed. E. Chauvenet and H. Gueylard found that the lowering of the f.p. of soln. of zirconium sulphate corresponded with a mol. wt. of 79·4 instead of 286·6. This is taken to mean that the salt is broken down into four mol. species, and this is considered to agree with a salt of the composition $ZrOSO_4.H_2SO_4$.

J. J. Berzelius did not observe the formation of an acid sulphate when zirconium sulphate is crystallized from its soln. in conc. sulphuric acid; and this also applies to the observations of R. Hermann, S. R. Paykull, and M. Weibull. H. Rose also said that the normal sulphate can be crystallized unchanged from sulphuric acid; but O. Hauser showed that a well-defined acid salt can be obtained from the sulphuric acid soln. of zirconium sulphate, and it appears to have been overlooked because the crystals of the acid salt are formed so slowly. O. Hauser found that the solubility of zirconium sulphate in water of different conc. slowly decreases with increasing conc. of acid, as indicated in Fig. 6, and then begins to increase, rising to a maximum when 61 per cent. SO_3 is present; after that the solubility slowly diminishes again. Soln. containing 61 to 64 per cent. of sulphur trioxide deposit in 4 to 12 days crystals of an acid sulphate, **trihydrated zirconium dihydro-trisulphate,** $Zr(SO_4)_2.H_2SO_4.3H_2O$, or $ZrSO_4(HSO_4)_2.3H_2O$, which O. Hauser considers to be a *hydrosulphatozirconic acid,* $H_2[Zr(SO_3)_3]3H_2O$; for, on electrolysis, it furnishes a complex anion, $H_2[Zr(SO_4)_3]=2H+Zr(SO_4)''_3$. A temp. near 40° is favourable to the production of this acid sulphate, but it can be obtained at 22° in a similar way; the solubility curve at 22° is similar to that at 40°. The crystals of this salt furnish monoclinic prisms which are very hygroscopic, and which rapidly deliquesce in air to form the normal tetrahydrate, $Zr(SO_4)_2.4H_2O$. The sp. gr. is 2·02 at 19°. Soln. containing more than 70 per cent. SO_3 deposit crystals of **monohydrated zirconium dihydrotrisulphate,** $Zr(SO_4)_2.H_2SO_4.H_2O$. On melting the trihydrate with much conc. sulphuric acid in a glass tube, and allowing the whole to stand for some days, the monohydrate is deposited as a compact crystalline powder of sp. gr. 2·05, which is even more hygroscopic than the trihydrate. E. Chauvenet reported acid zirconium sulphates with $ZrOSO_4:SO_3:H_2O$ =1:1:0, 1:1:1, and 1:1:4.

According to J. J. Berzelius, a conc. soln. of normal alkali dissolves zirconium

FIG. 6.—Solubility of Zirconium Oxide in Sulphuric Acid.

hydroxide, and when the soln. is evaporated, it furnishes a gum-like mass, which, when dried, is white and opaque. It swells up like alum when heated, and loses water. The gum-like mass dissolves in a little water, but the soln. precipitates a basic salt when treated with a large proportion of water. The product is also insoluble in acids. Analyses corresponded with $ZrO_2.SO_3$, or **zirconyl sulphate,** $ZrO.SO_4$. O. Kulka obtained a similar product by neutralizing with ammonia the soln. of zirconium hydroxide in zirconium sulphate. R. Ruer and O. Hauser consider that the soln. is really a suspension of colloidal hydroxide in the soln. of the sulphate. The fresh hydroxide precipitated in the cold is the most soluble form. Conc. soln. of the sulphate at 60° take up $ZrO_2 : SO_4 = 1.15 : 1$ in several days. O. Hauser could not prepare zirconyl sulphate by evaporating this soln. E. Löwenstein found the vap. press. of the hydrate to be a continuous function of the contained water; there is no break in the curve.

E. Chauvenet claimed to have made **tetrahydrated zirconyl sulphate,** $ZrOSO_4.4H_2O$, by evaporating a mixture of equimolar parts of zirconia and sulphuric acid; the same salt is precipitated when 2 mols of potassium hydroxide are added to one mol of the normal sulphate, assumed to be an acid zirconyl sulphate : $ZrOSO_4.H_2SO_{4aq.} + 2KOH = ZrOSO_4 + K_2SO_{4aq.} + 2H_2O$; and when a mixture of soln. of acid zirconyl sulphate and ammonium sulphate is allowed to stand a few days, the tetrahydrate is again deposited. When exposed to dried air, it furnishes **dihydrated zirconyl sulphate,** $ZrOSO_4.2H_2O$; and when dried at 150°, it becomes anhydrous, $ZrOSO_4$. He also obtained **monohydrated zirconyl sulphate,** $ZrOSO_4.H_2O$. The hemihydrate, $2ZrO.SO_4.H_2O$, which R. Ruer and M. Levin represented by $H_2(Zr_2O_3)(SO_4)_2$, or **hydrodisulphatodizirconylic acid,**

$$H-SO_4-Zr{\textstyle{\diagdown O \atop \diagup O}}$$
$$H-SO_4-Zr{\textstyle{\diagdown O}}$$
corresponds with the complex salts isolated by A. Rosenheim and P. Frank—*vide infra.* E. Chauvenet mixed varying proportions of zirconium oxide and sulphuric acid; dried the products at 200°, and measured their sp. gr. in nitrobenzene at 12·4°. He obtained with the molar ratio $H_2SO_4 : ZrO_2 = 1 : n$,

n			0·125	0·250	0·50	0·625	0·75	0·875	1	1·125	1·20
Sp. gr.			2·05	2·20	2·50	2·78	3·02	3·20	3·40	3·45	3·47

n			1·25	1·30	1·40	1·50	1·75	2·0	2·5	3·0
Sp. gr.			3·49	3·52	3·57	3·62	3·65	3·69	3·79	3·87

The breaks on the curve indicated the existence of normal sulphate, zirconyl sulphate, and basic sulphates with $Zr(SO_4)_2 : ZrO_2 = 5 : 7, 3 : 5, 1 : 2$, and $1 : 3$; but no signs of the 2 : 1, 7 : 5, 3 : 4, or 1 : 5 compounds or of the acid salt $H_2Zr(SO_4)_3$. By measuring the change in the electrical conductivity of a soln. of normal zirconium sulphate during the addition of $0.001N$-NaOH, the results furnished a curve with two breaks corresponding with the existence of zirconyl sulphate, and the 1 : 3- and the 3 : 5-salts. The 5 : 7-salt can be regarded as $5ZrOSO_4.ZrO_2$, or **zirconium heptoxypentasulphate,**

$$SO_4.ZrO.SO_4.ZrO.SO_4.ZrO.SO_4.ZrO.SO_4$$
$$ZrO\text{————————}O\text{————}ZrO$$
The *dodecahydrate,* $(ZrO.SO_4)_5ZrO_2.12H_2O$, is precipitated when alcohol is added to a conc. soln. of ordinary zirconium sulphate. The salt becomes anhydrous at 100°. The 3 : 5-salt can be represented $3ZrOSO_4.ZrO_2$, *i.e.* **zirconium pentoxytrisulphate,** or

$$SO_4.ZrO.SO_4.ZrO.SO_4$$
$$ZrO\text{————}O\text{————}ZrO$$
and the *octohydrate* is a product of the hydrolysis of the precipitate obtained when

potassium sulphate is added to a soln. of zirconyl chloride. The octohydrate becomes anhydrous at 100°. As a product of the further hydrolysis of this salt, E. Chauvenet obtained the 1 : 3-salt or $ZrOSO_4.ZrO_2$, $i.e.$ **zirconium trioxysulphate,**
$$SO_4 < \frac{Zr}{Zr} \lessgtr \frac{O}{O}$$
as an $octohydrate$, which becomes anhydrous at 100°.

According to J. J. Berzelius, when alcohol is added to an aq. soln. of normal zirconium sulphate, and the precipitate washed first with alcohol and then with water, a salt having the composition $3ZrO_2.2SO_3(nH_2O)$, possibly $zirconium$ $tetroxydisulphate$, $Zr_3O_4(SO_4)_2(nH_2O)$, or $Zr_3(OH)_8(SO_4)_2(mH_2O)$,

$$\begin{matrix} O_{\searrow}Zr \\ O_{<}^{<} Zr_{>}SO_4 \\ O_{\lessgtr} Zr_{>}^{>} SO_4 \\ O^{\nearrow} Zr \end{matrix} \qquad \begin{matrix} (HO)_3 {\equiv} Zr \\ (HO)_2 {=} Zr_{>}^{>} SO_4 \\ (HO)_3 {\equiv} Zr \end{matrix}$$

is formed.

The same salt was said to be produced when the soln. of zirconyl chloride was largely diluted with water. The white flakes are insoluble in water, and soluble in hydrochloric acid. The composition of this salt agrees with E. Chauvenet's 1 : 2-salt, and the salt is said to be obtained when potassium sulphate is added to a soln. of zirconyl chloride, the $octohydrate$, $2ZrOSO_4.ZrO_2.8H_2O$, is precipitated. It loses all 8 mols. of water at 100°, and becomes anhydrous. S. R. Paykull, and H. Endemann likewise obtained a product of the same composition. O. Hauser found the b.p. of soln. of zirconium dihydrotrisulphate slowly decreased on prolonged heating, and he attributed this to the formation of the acid salt, **pentahydrated dizirconium dihydroxytrisulphate,** $2ZrO_2.3SO_3.5H_2O$, or

$$\begin{matrix} HO{-}Zr {<\!\!<}^{\diagup SO_4}_{\diagdown SO_4} \\ HO{-}Zr {<\!\!<}_{\diagdown SO_4} \end{matrix} \qquad \qquad \begin{matrix} O < \frac{Zr}{Zr} {>}^{\diagup SO_4}_{\diagdown SO_4} \end{matrix}$$

Zirconium dihydroxytrisulphate.   Zirconium oxytrisulphate.

which separates in crystals from very conc. soln.—say 50 grms. of anhydrous zirconium sulphate and 60 grms. of water. The salt is washed with a little cold water and dried over conc. sulphuric acid. Dil. soln. do not give this precipitate, but a flocculent mass of indefinite composition. The sp. gr. of the salt is 2·834 at 19°; it is soluble in water; and readily soluble in acids. The aq. soln. has a feebly acid reaction. The zirconium is imperfectly precipitated as hydroxide from the aq. soln. by aq. ammonia and alkali-lye. The anhydride, **zirconium oxytrisulphate,** $2ZrO_2.3SO_3$, or $Zr_2O(SO_4)_3$, was prepared by O. Hauser by heating the hydrated salt to 300°. If the salt be allowed to stand in contact with water for a long time, it furnishes a salt more basic than zirconyl sulphate, which O. Hauser and H. Herzfeld represent as $4ZrO_2.3SO_3.15H_2O$ when dried over sulphuric acid of sp. gr. 1·256. The salt may be regarded as **decahydrated zirconium decahydroxytrisulphate,** $Zr_4(OH)_{10}(SO_4)_3.10H_2O$,

$$\begin{matrix} (HO)_2 {=} Zr {<}^{SO_4 {-} Zr(OH)_3}_{SO_4} \\ (HO)_2 {=} Zr {<}_{SO_4 {-} Zr(OH)_3} \end{matrix} + 10H_2O$$
or some intermediate stage, $HO.ZrO.SO_4.ZrO.SO_4.ZrO.SO_4.ZrO.OH + 14H_2O$. O. Hauser found that the same salt is formed when soln. containing between $Zr(SO_4)_2 : H_2O = 1 : 7$ and $1 : 120$ are allowed to stand for about 10 hrs. at 39·5°. Soln. with less than the ratio 3 : 20 remain clear. The conc. of the soln. required for the deposition of this salt depends on the temp.; the lower the temp., the greater the conc. required for its formation. The speed of the reaction is small,

and is greater the higher the temp. The compound is not produced above 50°. The composition of the salt may be represented by $ZrO(OH)_2.3ZrOSO_4.13H_2O$ in agreement with the fact that very dil. soln. are opalescent, and yield colloidal zirconium hydroxide when dialyzed. This may mean that the salt is further hydrolyzed by dilution. If very dil. soln. of this basic sulphate be kept for a long time at 64°, (i) the crystalline salt is no longer deposited at a lower temp.; (ii) the soln. gives a precipitate with hydrogen dioxide only after standing for some time; and (iii) a small proportion of oxalic acid gives no precipitate. The time required to inaugurate the indifferent stage depends on the conc. of the soln. Conc. soln. which have been heated and then diluted behave differently from those which have been diluted and then heated. O. Hauser and H. Herzfeld found that the decahydroxytrisulphate is so well-defined a chemical individual that it can be used in at. wt. determinations. It furnishes microscopic, monoclinic, acicular crystals of sp. gr. 2·50, and it is very stable towards dil. acids. The solubility in water is less than 0·009 per cent. When dried over sulphuric acid of increasing conc., the loss of water is continuous until **dihydrated zirconium decahydroxytrisulphate,** $Zr_4(OH)_{10}(SO_4)_3.2H_2O$, is formed. The process of dehydration is not reversible. If the salt be heated at 105°–115° for a long time, **zirconium decahydroxytrisulphate,** $Zr_4(OH)_{10}(SO_4)_3$, is formed. Attempts to replace the hydroxyl by chlorine gave indefinite results. O. Hauser and H. Herzfeld represent the composition of the salt $2ZrO_2.3SO_3.5H_2O$ by the formula $H_4[Zr_4(SO_4)_6(OH)_8].4H_2O$ in order to explain its acid properties and its ready conversion into either of the two salts described below. The 4 mols of water are lost at 225°. The salt $4ZrO_2.3SO_3.14H_2O$ is represented by the formula $Zr_4(SO_4)_3(OH)_{10}.9H_2O$, and it can be prepared in another form by dissolving zirconium sulphate tetrahydrate in cold water and keeping the 2 per cent. soln. for several days, when the salt is deposited in the form of needles differing only from the crystals of the first form in their optical properties. The first is not decomposed by boiling water, whilst the second loses part of its sulphuric acid. The more basic salt, $\{Zr_8(SO_4)_5(OH)_{22}\}8H_2O$, is prepared by dissolving anhydrous zirconium sulphate in five times its weight of water and precipitating with alcohol. The precipitate is then dissolved in a little warm water and dialyzed, and in the course of a few days the basic salt separates in the form of very characteristic spherical crystals which do not lose their shape when dehydrated. According to E. H. Rodd, when a soln. of the basic chloride $Zr_5O_8Cl_4.22H_2O$ is treated with sulphuric acid, or a soluble sulphate, a white, curdy, basic sulphate is precipitated. If ammonium sulphate or magnesium sulphate is used, the precipitate first formed redissolves until about half the eq. quantity of sulphate has been added. With a quantity of sulphate eq. to the chlorine in the basic chloride, the zirconium appears to be completely precipitated. The basic sulphate again redissolves in excess of the precipitant. In the case of sulphuric acid the precipitate becomes permanent with a few drops of acid; it redissolves, however, in a large excess. To make the basic sulphate, the oxychloride is dissolved in 30 times its weight of water and 2 molar proportions of sulphuric acid are added for each molar proportion of the basic sulphate. W. Rosenhain and E. H. Rodd made a basic sulphate by adding sodium hydroxide or ammonia to a soln. containing zirconium sulphate and hydrochloric acid until the acidity of the soln. had been so far neutralized that a permanent white precipitate began to form, and then allowing precipitation to continue without further addition of alkali. The air-dried precipitate had the composition $Zr_5O_8(SO_4)_2.14H_2O$,

$$SO_4{=}ZrO.ZrO.O.ZrO.O.Zr{=}SO_4 \quad \text{or} \quad SO_4{<}{\overset{ZrO.O}{\underset{ZrO.O}{>}}}Zr{<}{\overset{O.ZrO}{\underset{O.ZrO}{>}}}SO_4$$
$$O\text{------}O\text{------}O$$
i.e. **zirconyl disulphatozirconate.** R. Ruer, and M. Levin boiled for a time a soln. of zirconyl chloride mixed with a molar proportion of sulphuric acid, and obtained a product with 48·65 per cent. ZrO_2 and 19·83 per cent. SO_3, which corresponds

with no definite at. ratio ; but E. H. Rodd boiled a soln. of 6 grms. of octohydrated zirconyl chloride with 500 c.c. of water for 6 hrs., and an eq. of dil. sulphuric acid was added to the opalescent soln. About 60 per cent. of the zirconia in soln. was precipitated as a slimy mass which, when washed and dried in air, formed a hard glassy cake with a composition corresponding with disulphatozirconyl zirconate. This salt, however, when dried is insoluble in sulphuric acid, is not attacked by ammonia, and gives, on ignition, a hard, granular zirconia ; the basic sulphate prepared from the basic chloride, $Zr_5O_8Cl_4.22H_2O$, is soluble in sulphuric acid, decomposed by ammonia, and, on ignition, gives a loose, white powder.

H. Endemann added alcohol to a conc. aq. soln. of the sulphate and obtained a basic sulphate with the composition $7ZrO_2.6SO_3.14H_2O$, or *zirconium octoxyhexasulphate*, $Zr_7O_6(SO_4)_6.14H_2O$, or $Zr_7(OH)_{16}(SO_4)_6.6H_2O$. The product dissolves in a small quantity of water, a large excess precipitates a more basic salt leaving a more acidic salt in soln. When the alcoholic precipitate is moistened with water, alcohol is given off, making it probable, said H. Endemann, that some alcohol takes the place of water of crystallization. It will be observed that both these salts have the same general formula : $Zr_nO_{n+1}(SO_4)_{n-1}$, or $Zr_n(OH)_{2n+2}(SO_4)_{n-1}$, and an indefinite number of these might be obtained by varying the conc. of the soln. : $nZr(SO_4)_2+2(n+1)H_2O = (n+1)H_2SO_4+Zr_n(OH)_{2n+2}(SO_4)_{n-1}$. They probably represent varying stages in the hydrolysis of normal zirconium sulphate ; and the establishment of their chemical individuality requires something more than analysis.

Complex products of variable composition have been obtained by dissolving zirconia in fused potassium hydrosulphate ; and by mixing soln. of potassium sulphate and zirconium sulphate. According to J. J. Berzelius,[3] molten potassium hydrosulphate dissolves zirconia, forming a clear liquid ; if a large excess of the hydrosulphate be present, the cold mass dissolves completely in water, but if otherwise, the product is decomposed by water into potassium hydrosulphate which dissolves, and a complex potassium sulphate which remains undissolved. B. Franz boiled the cold cake with dil. sulphuric acid and obtained an insoluble basic zirconium sulphate. C. M. Warren fused zirconia mixed with five times its weight of potassium hydrosulphate, dissolved the cold mass in an excess of sulphuric acid, evaporated the soln. to remove most of the sulphuric acid, and mixed the cold product with cold water. The undissolved portion had the composition $3K_2O.3ZrO_2.7SO_3.9H_2O$; the aq. soln. on evaporation furnished a crystalline powder with the composition $2K_2O.6ZrO_2.7SO_3.9H_2O$. There is nothing, however, to show that chemical individuals are involved.

According to J. J. Berzelius, when potassium sulphate in crystals or as a sat. soln. is added to neutral soln. of zirconium salts the whole of the zirconium in soln. is gradually precipitated as a crystalline basic double sulphate ; if the soln. be acidic, only part of the zirconium is precipitated, but all is deposited when the soln. is neutralized with potassium hydroxide. A similar precipitate is formed when a soln. of zirconium sulphate is mixed with any salt of potassium. J. J. Berzelius, and R. Hermann represented the composition of the product $3ZrO_2.SO_3.xH_2SO_4$. The product is sparingly soluble in water, and is redeposited when potassium sulphate is added ; if the precipitate be washed with only a small portion of water, it dissolves in acids, especially when aided by heat, but if it be thoroughly washed, or boiled in water, it becomes nearly insoluble in water or acids, and requires conc. acid to dissolve it. When ignited, it loses water and sulphuric acid, and is virtually insoluble in hot conc. sulphuric acid. Soln. of ammonia or potassium carbonate dissolve the salt imperfectly ; a soln. of ammonium carbonate dissolves it, but on boiling deposits it again in its insoluble condition. C. M. Warren, and S. R. Paykull made some observations on this subject.

A. Rosenheim and P. Frank reported the formation of **potassium zirconium trioxydisulphate,** $Zr_2O_3(KSO_4)_2.8H_2O$, in small crystalline plates, when a soln. of normal potassium sulphate is added to a cold aq. soln. of zirconium sulphate ; and **rubidium zirconium trioxydisulphate,** $Zr_2O_3(RbSO_4)_2.15H_2O$, and **cæsium zirconium trioxydisulphate,** $Zr_2O_3(CsSO_4)_2.11H_2O$, were made in a similar way.

O. Hauser and H. Herzfeld added that the composition of these basic salts is more complicated than this. In general, the basic double salts of zirconium sulphate, like the basic zirconium sulphates, form colloidal soln. From the hot aq. soln., gels are precipitated by electrolytes, and dil. acids. The gels are probably colloidal zirconium hydroxide which dissolves only slowly in acids. The composition of the basic double salts of zirconium sulphates is influenced to an unusual degree by the temp. and conc. of the soln. In general, the product which separates from a weakly acid soln. is more basic than that from a strongly acid soln. According to R. Ruer, soln. of both zirconium oxychloride, and nitrate when treated with oxalic acid give precipitates soluble in excess; the reaction does not occur with sulphates because the zirconium is masked, being a constituent of the anion, not the cation. When the soln. is aged, and hydrolysis has progressed until metazirconic acid is formed, the sulphates then give the reaction with oxalic acid. Aged soln. of the sulphate, if warm, give precipitates with sulphates which are soluble in an excess of the reagent; but freshly prepared soln. of the oxychloride, or nitrate give no precipitates with a sulphate. The different behaviour of aged and freshly prepared soln. is another complication which hinders the acquisition of clear definite knowledge about these salts. A. Rosenheim and P. Frank prepared hydrated **potassium zirconium tetrasulphate,** $Zr(KSO_4)_4.3H_2O$, but A. Rosenheim and J. Pinsker showed that the proportion of water of crystallization is variable. The salt is obtained in acicular crystals by adding an excess of freshly precipitated zirconium hydroxide to a hot conc. soln. of potassium hydrosulphate. The salt is hydrolyzed by water at 30°, with the formation of basic salts, but no product of definite composition was isolated. A. Rosenheim and P. Frank reported the formation of **sodium zirconium tetrasulphate,** $Zr(NaSO_4)_4.4H_2O$, in acicular crystals when a cold acid soln. of sodium hydrosulphate is sat. with freshly precipitated zirconium hydroxide. The aq. soln. is clear, but slowly hydrolyzes when boiled. A. Rosenheim and J. Pinsker obtained the corresponding hydrated **ammonium zirconium tetrasulphate,** $Zr(NH_4SO_4)_4.5H_2O$, from the mother-liquor in the preparation of ammonium zirconium octohydroxyhexasulphate (q.v.). The salt is deposited only when the acidity of the soln. has been increased sufficiently by the separation of the basic salt. A. Rosenheim and J. Pinsker obtained **tetrapotassium zirconium octohydroxypentasulphate,** $K_4Zr_4(OH)_8(SO_4)_5.8H_2O$, by mixing conc. soln. of zirconium sulphate and normal potassium sulphate. O. Hauser and H. Herzfeld prepared a potassium zirconyl sulphate of definite composition, $K_2Zr_4(OH)_8(SO_4)_5$, **dipotassium zirconium octohydroxypentasulphate,** by dropping a sat. soln. of potassium sulphate into a conc. soln. of tetrahydrated zirconium sulphate acidified with sulphuric acid. The corresponding zirconium sulphuric acid was not prepared. A. Rosenheim and J. Pinsker obtained a crystalline mass of **ammonium zirconium octohydroxyhexasulphate,** $(NH_4)_4Zr_4(OH)_8(SO_4)_6.4H_2O$, by evaporating over conc. sulphuric acid, mixed soln. of 10 grms. anhydrous zirconium sulphate in 10 c.c. of water, and 14 grms. of ammonium sulphate in 25 c.c. of water. The mother-liquid remaining after the crystalline crusts have separated, furnishes ammonium zirconium tetrasulphate. This basic salt is considered to be the ammonium salt of a zirconium sulphuric acid obtained by O. Hauser and H. Herzfeld. E. Chauvenet and H. Gueylard measured the f.p. and heats developed on mixing soln. of potassium or sodium hydroxide, or aq. ammonia with soln. of zirconium sulphate. The resulting curves indicated the existence of **sodium dizirconyl hexasulphate,** $2ZrOSO_4.SO_3.3Na_2SO_4.8H_2O$; **sodium trizirconyl hexasulphate,** $3ZrOSO_4.SO_3.2Na_2SO_4.7H_2O$; and **sodium trizirconyl tetrasulphate,** $3ZrOSO_4.Na_2SO_4$; **potassium trizirconyl tetrasulphate,** $3ZrOSO_4.K_2SO_4.8H_2O$; **ammonium trizirconyl tetrasulphate,** $3ZrOSO_4.(NH_4)_2SO_4$; **ammonium zirconyl trisulphate,** $ZrOSO_4.SO_3.(NH_4)_2SO_4.3H_2O$; and **ammonium zirconyl tetrasulphate,** $ZrOSO_4.SO_3.2(NH_4)_2SO_4.3H_2O$, A. Rosenheim and J. Pinsker did not succeed in isolating basic sodium zirconium sulphates on account of their great solubility. L. Fernandes prepared **thallous zirconium**

tetrasulphate, $2Tl_2SO_4.Zr(SO_4)_2.4H_2O$; **thallous zirconium pentasulphate,** $Tl_2SO_4.2Zr(SO_4)_2.8H_2O$; and **thallous zirconium enneasulphate,** $7Tl_2SO_4.2Zr(SO_4)_2$, by the crystallization of a mixed soln. of the component salts—the first by cooling hot soln., the last by evaporation at a low temp.   The solubility of the enneasulphate expressed in grams of zirconia per 100 c.c. of water was found to be :

	0°	10°	20°	30°	40°	60°	80°	100°
ZrO_2 . . .	6·2	6·2	6·5	7·2	8·5	15·7	24·5	32·0

§ 13. Zirconium Carbonates

There is no evidence of the formation of normal *zirconium carbonate* or of normal *zirconyl carbonate*. N. J. Berlin,[1] and S. R. Paykull found that zirconium hydroxide, $ZrO_2.H_2O$, readily absorbs carbon dioxide from the atm. F. P. Venable and A. W. Belden found that basic carbonates of widely varying composition are formed when carbon dioxide is passed over the hydroxide at 100°–150°. Over 16 per cent. of the gas may be so absorbed, and a part is given off when the product is similarly heated in a current of air ; 7 per cent. of carbon dioxide may be absorbed when the gas is bubbled through water in which the hydroxide is suspended. M. H. Klaproth, and L. N. Vauquelin regarded the white powder which is obtained when a cold soln. of a zirconium salt is treated with potassium carbonate as a

carbonate; and R. Hermann's analysis of the precipitate washed with cold water, and dried at 17·5° over sulphuric acid, corresponded with $3ZrO_2.CO_2.6H_2O$. A. Mandl also prepared a basic carbonate by passing carbon dioxide through an aq. soln. of zirconium nitrate and ammonium carbonate. The white flocculent basic carbonate precipitated by the alkali carbonate is soluble in an excess of the precipitant; and when boiling water is poured over the precipitate carbon dioxide is evolved.

According to J. J. Berzelius, zirconium hydroxide dissolves very slowly and imperfectly in a soln. of ammonium carbonate, but the basic carbonate dissolves more readily. When the soln. is boiled zirconium hydroxide, free from carbonate, is deposited—as a white powder from the soln. in ammonium hydrocarbonate, and in gelatinous masses from the soln. of the normal carbonate. It is assumed that the solute is a basic *ammonium zirconium carbonate*. Analogous results were obtained with the alkali carbonates, forming *sodium zirconium carbonate*, or *potassium zirconium carbonate*. No chemical individual has been definitely established.

§ 14. Zirconium Nitrates

J. J. Berzelius [1] evaporated a soln. of zirconium hydroxide in nitric acid, and obtained a yellow, sticky mass with a sour taste, and which, when dried at a temp. below 100°, is completely soluble in water. The aq. soln. can dissolve a large additional quantity of zirconium hydroxide, forming a basic salt. Consequently, a comparatively large quantity of alkali-lye can be added to a soln. of the nitrate before a permanent precipitate occurs. L. N. Vauquelin said that water dissolves only a portion of the residue left on evaporating the nitric acid soln. to dryness. Basic nitrates, $3ZrO_2.2N_2O_5$, and $ZrO_2.N_2O_5$, were reported by R. Hermann, and S. R. Paykull, but these products represent indefinite stages in the hydrolysis of the nitrate. M. Weibull evaporated a soln. of zirconium hydroxide in nitric acid at 65°, and obtained a white powder with the composition $ZrO(NO_3)_2.2H_2O$, **dihydrated zirconyl nitrate ;** A. Rosenheim and P. Frank obtained a crystalline mass of the same composition by evaporating the soln. over sulphuric acid. M. Weibull evaporated the soln. at 100°, and obtained a glassy mass with the composition of **zirconyl hydroxynitrate,** $ZrO(OH)NO_3$. When the powdered zirconyl nitrate is dissolved in boiling alcohol and the soln. treated with ether, a white powder with the composition $Zr_2O_3(NO_3)_2.5H_2O$, or **dihydrated zirconyl hydroxynitrate,** $ZrO(OH)NO_3.2H_2O$, is formed (*vide infra*). It is readily soluble in water. E. Chauvenet and L. Nicolle could not make the normal nitrate by evaporating a soln. of zirconium nitrate in nitric acid in a current of carbon dioxide sat. with nitric acid fumes. The dehydration is always accompanied by the loss of nitric acid. The product was always **hemiheptahydrated zirconyl nitrate,** $ZrO(NO_3)_2.3\frac{1}{2}H_2O$, when the evaporation was conducted below 10°, and $ZrO(NO_3)_2.2H_2O$, when above that temp. (*vide infra*). A. Mandl failed to make the normal nitrate by evaporating a nitric acid soln. of zirconium hydroxide at 100°; similar results were obtained when the soln. was mixed with potassium nitrate, and no double salt was formed. A. Müller was unable to make a nitrate of constant composition, and he said that during the evaporation of soln., the salt undergoes hydrolysis, nitric acid escapes, and the product obtained is always a mixture of the hydroxide and nitrate in varying proportions. The products

when treated with water furnish opalescent, partly colloidal soln. Reports of *pentahydrated zirconium nitrate*, $Zr(NO_3)_4.5H_2O$, by R. Hermann, M. Weibull, S. R. Paykull, and A. Rosenheim and P. Frank, formed in hygroscopic prisms by evaporating a nitric acid soln. of zirconium hydroxide over phosphorus pentoxide and sodium hydroxide, probably refer to an acidic zirconyl nitrate, $ZrO(NO_3)_2.2HNO_3.4H_2O$. Commercial zirconium nitrate is an indefinite basic salt. E. Löwenstein measured the vap. press. of the so-called pentahydrated zirconium nitrate, when confined over sulphuric acid of different conc., and found that the dihydrated and anhydrous salts were formed.

C. L. Wagner examined the gradual hydrolysis of soln. of zirconium nitrate by means of the ultramicroscope and obtained results like those with ferric chloride. W. Ramsay and F. L. Usher exposed soln. of zirconium nitrate to radium emanation and obtained carbon oxide gases which he attributed to the degradation of zirconium to carbon. The hypothesis has not been confirmed. E. Chauvenet and L. Nicolle found that dihydrated zirconyl nitrate remains unaltered in air, and does not fume if entirely freed from adsorbed nitric acid. A mol of the dihydrate was mixed with n mols of water and the heat of soln. of the mixture determined :

n	0	1	1·5	2·17	2·76	4
Heat of soln. . .	2·17	−0·50	−1·92	−2·77	−3·95	−5·90

The resulting curve gave one break corresponding with the hemiheptahydrate. This hydrate is readily formed at 0° ; it is unstable at 10° ; and it effloresces at ordinary temp. forming the dihydrate. When zirconyl nitrate is dissolved in water it is slowly hydrolyzed, forming a precipitate with the composition $ZrO(NO_3)_2.ZrO_2.nH_2O$, or $ZrO(HO)NO_3.mH_2O$. The rate of hydrolysis is represented by the conductivity of the $0·01N$-soln. at 29·5°. A few minutes after the preparation the conductivity was 505·19, which rose to 554 in a few hours, and to 600 in a few days. The conductivity thereafter remained constant for some months. The $0·01N$-soln. of zirconyl nitrate was treated with a $0·01N$-soln. of sodium hydroxide, and the conductivity determined after each addition. The resulting curve had two breaks corresponding respectively with the reactions $ZrO(NO_3)_2+NaOH=NaNO_3+ZrO(OH)NO_3$, and $ZrO(NO_3)_2+2NaOH=2NaNO_3 +ZrO_2+H_2O$. Cryoscopic measurements gave the mol. wt. 92·9 instead of 266·6 ; this means that the original mol. breaks down into three parts. Hence, it was inferred that the dissociation of the soln. yields $Zr(OH)_3NO_3.HNO_3$. E. Chauvenet and L. Nicolle measured the effect of heating zirconyl nitrate at different temp., and found that at 120° in the presence of nitric acid vap., the dehydration is accompanied by a loss of nitric acid to form a basic nitrate $3ZrO(NO_3)_2.ZrO_2.7H_2O$; and when the dehydration occurs in air, there is formed at 110°, the basic nitrate $2ZrO(NO_3)_2.ZrO_2.7H_2O$; at 150°, $ZrO(NO_3)_2.2ZrO_2.4H_2O$; at 215°, $ZrO(NO_3)_2. 7ZrO_2.5H_2O$; at 250°, $ZrO(NO_3)_2.10ZrO_2.4H_2O$; and above this temp., zirconia is formed. These products probably represent mixtures and not chemical individuals. W. Biltz dialyzed soln. of zirconyl nitrate and found that in about 5 days the outside water was free from nitric acid ; and the resulting hydrosol was clear in transmitted light and turbid in reflected light. The sol. is flocculated by electrolytes ; and the gold number is between 0·046 and 0·09. S. Meyer measured the magnetic susceptibility of zirconium nitrate. A. Kolb prepared **dihydrated zirconyl diamminonitrate**, $ZrO(NO_3)_2.2NH_3.2H_2O$, by the action of ammonia on zirconyl nitrate. The white crystalline mass is slightly hygroscopic, and is stable in air.

§ 15. Zirconium Phosphates

The solubilities of zirconium in phosphoric acid, and of zirconia in fused sodium ammonium phosphate have been previously discussed; similarly also with the adsorption of phosphoric acid by colloidal zirconium dioxide. P. Hautefeuille and J. Margottet [1] heated zirconia with phosphoric acid to a temp. short of dehydration and found 100 parts of the acid dissolved 2 parts of the oxide. On cooling, two kinds of octahedral crystals separated out—one kind were doubly refracting, the other kind, singly refracting. The empirical formula was $2ZrO_2.P_2O_5$, or $(ZrO)_2P_2O_7$, **zirconyl pyrophosphate.** The crystals were not attacked by acids or potassium hydrosulphate, but were easily decomposed by fusion with alkali carbonates, giving insoluble alkali zirconates which could be freed from phosphoric acid by washing. A. Knop fused zirconia with sodium ammonium phosphate at a high temp. for some time, and lixiviated the cold mass with dil. hydrochloric acid. The rectangular parallelopipedal crystals resembled those of sodium zirconium phosphate. The analyses corresponded with $ZrO_2.P_2O_5$, corresponding either with **zirconium pyrophosphate,** ZrP_2O_7, or **zirconyl metaphosphate,** $ZrO(PO_3)_2$. R. Hermann obtained a product with the composition $ZrO_2.P_2O_5$, by dropping a soln. of zirconyl chloride into one of ammonium dihydrophosphate. M. Weibull added an aq. soln. of zirconyl chloride to an excess of a soln. of sodium hydrosulphate and obtained a white precipitate with the composition $ZrP_2O_7.2H_2O$; and a similar product, $ZrP_2O_7.1\frac{1}{2}H_2O$, was obtained by dropping a soln. of zirconium sulphate into one of sodium dihydropyrophosphate. These results show that when a soln. of a zirconyl salt is added to an excess of a soln. of a phosphate, either zirconium pyrophosphate, or zirconyl metaphosphate is formed—analysis does not distinguish between them. E. Wedekind and H. Rheinholdt supposed that **zirconium hydrophosphate,** $Zr(HPO_4)_2$, is formed. C. E. F. Lundell and H. B. Knowles assumed that the secondary phosphate is precipitated by sodium hydrophosphate in acid soln., and when the product is ignited, it yields the normal pyrophosphate. J. H. de Boer and A. E. van Arkel said that zirconium is precipitated as the hydrophosphate from strongly acidic soln., which is insoluble in hydrochloric acid but soluble in hydrofluoric acid. Hence zirconium can be separated as the hydrophosphate from all metals except hafnium. The hydrophosphate is soluble in oxalic acid, and in conc. sulphuric and phosphoric acids only when freshly precipitated. The oxalic acid soln. is decomposed by heat or by the addition of alcohol or the mineral acids, and the soln. in sulphuric or phosphoric acid is decomposed by dilution. Alkali-lye converts the phosphate into hydroxide superficially, but complete decomposition is obtained in the presence of a substance capable of dissolving the hydroxide in alkaline soln., thus the aliphatic oxy-acids— *e.g.* tartaric, malic or lactic acid—alcohols with at least two hydroxyl groups on neighbouring carbon atoms—*e.g.* glycerol, dextrose, sucrose, pyrocatechol, and pyrogallol—and hydrogen dioxide. The hydrogen dioxide soln. precipitates the hydroxide when heated, and a perzirconate when alcohol is added; the other soln. yield the hydroxide when they are partially neutralized with acid—preferably after precipitating the phosphoric acid with barium chloride. G. von Hevesy and K. Kimura found the **zirconyl dihydrophosphate,** $ZrO(H_2PO_4)_2$, is precipitated from 6N-HCl soln.; and its solubility is 0.00012 and 0.00023 mol per litre respectively in 6N- and 10N-HCl. On ignition, the phosphate loses 2 mols. of water forming zirconyl metaphosphate. The relation between the temp. and the progress

of the reaction, $ZrO(H_2PO_4)_2 \rightarrow ZrO(PO_3)_2$, and similarly with the hafnium salt, are shown in Fig. 7.

R. Hermann, and S. R. Paykull mixed soln. of sodium hydrophosphate and zirconyl chloride, and obtained a product with the composition $5ZrO_2.4P_2O_5.8H_2O$; M. Weibull mixed soln. of zirconyl chloride and sodium phosphate and obtained a product with the composition $5ZrO_2.3P_2O_5.9H_2O$ when dried at 100° ; and by adding a soln. of zirconyl chloride to one of sodium phosphate or of phosphoric acid, the product had the composition $3ZrO_2.2P_2O_5.5H_2O$. These results show that a *basic zirconium phosphate* may be formed, but until the products are more closely examined, the conditions better defined, and the previous history of the zirconium salt soln. indicated, the nature of these phosphates cannot be stated.
FIG. 7.—The Effect of Temperature on the Reaction :
$RO(H_2PO_4)_2 \rightarrow RO(PO_3)_2$.
J. J. Berzelius found that zirconia dissolved slowly in molten sodium ammonium phosphate, and A. Knop kept the molten mixture at a white heat for two hours, and after washing the cold mass with dil. hydrochloric acid, and removing the amorphous portion, he obtained a mass consisting of small colourless crystals in the form of rectangular parallelopipeds which acted on polarized light. The composition corresponded with $Na_2O.4ZrO_2.3P_2O_5$, *i.e.* with $NaZr_2(PO_4)_3$, **sodium zirconium triorthophosphate,**

$$Na-PO_4 < \frac{Zr \equiv PO_4}{Zr \equiv PO_4}$$
L. Troost and L. Ouvrard obtained a similar salt by using sodium metaphosphate and sodium chloride as a flux. G. Wunder regarded the crystals as tetragonal combinations of prisms and basic pinacoids. A. Knop found the sp. gr. to be 3·12–3·14. When fused with potassium carbonate, crystalline zirconia was formed, but the phosphate is not decomposed by fused borax at a white-heat. L. Troost and L. Ouvrard found that when molten potassium metaphosphate is sat. with zirconia, zirconium chloride, or zirconium phosphate, and the cold mass extracted with acidulated water, the crystalline powder has an analogous composition, **potassium zirconium triorthophosphate,** $KPO_4(ZrPO_4)_2$. The trigonal crystals have a sp. gr. 3·18. Both salts are insoluble in simple acids and in aqua regia. L. Troost and L. Ouvrard also reported that a salt with the composition $6Na_2O.3ZrO_2.4P_2O_5$, corresponding with **sodium zirconium octa-orthophosphate,** $(Na_2PO_4)_2 = Zr\{PO_4 = Zr = (Na_2PO_4)_2\}_2$, is formed by dissolving zirconium chloride in a fused mixture of sodium chloride and molten sodium pyrophosphate and extracting the mass with water. The hexagonal plates are optically biaxial ; and they act slightly on polarized light ; the sp. gr. is 2·88 ; and the salt is soluble in acids. If a large proportion of sodium chloride be used in the preceding mixture, the product has a composition $4Na_2O.ZrO_2.2P_2O_5$, corresponding with **sodium zirconium tetra-orthophosphate,** $Zr(Na_2PO_4)_4$. The crystals act energetically on polarized light, and have longitudinal extinction. Their sp. gr. is 2·43 ; and they are soluble in acids. L. Troost and L. Ouvrard fused a zirconium salt with potassium pyrophosphate or potassium hydrophosphate and potassium chloride ; and on extracting the cold mass with water, they obtained a crystalline powder of the composition $K_2O.ZrO_2.P_2O_5$, corresponding with **potassium zirconium diorthophosphate,** $Zr(KPO_4)_2$. The hexagonal plates have a sp. gr. 3·08 ; they were soluble in hot conc. nitric acid. If a large proportion of potassium chloride be employed, the same salt is obtained along with another consisting of tetragonal crystals the composition of which was not determined. If potassium orthophosphate be used in place of the pyrophosphate, the results were

indefinite ; but if potassium chloride was also added, the same results were obtained as with the pyrophosphate. G. Saring reported **potassium calcium phosphatozirconate,** $Ca_3(PO_4)_2(CaO)_2(K_2O)_2.ZrO_2$, analogous with the corresponding phosphatosilicate.

CHAPTER XLIII

HAFNIUM

§ 1. The History of Hafnium and Celtium

In 1911, G. Urbain [1] announced the discovery of a new element in some residues remaining after the separation of the lutecium-ytterbium fractions of the rare earths. He called it **celtium.** Subsequent observations showed that all the evidence in favour of this element was worthless. In May, 1922, A. Dauvillier found that the X-ray spectrum of these residues was in agreement with the presence of an element, atomic number 72, and G. Urbain applied the old term to the new element. The neo-celtium was not obtained in sufficient quantity, or sufficiently purified, to enable any other unequivocal statement to be made of its properties. Meanwhile, January, 1923, D. Coster and G. von Hevesy [2] reported a new element, discovered during their investigation of the zirconium minerals in quest of an element belonging to the zirconium family, and with an at. number 72, to fill the corresponding gap in the periodic table. The at. wt. is between 174 and 180. The new element was called **hafnium,** Hf—from *Hafnia*, an ancient name for Copenhagen. G. von Hevesy has summarized the known facts about hafnium in his *Recherches sur les propriétés du hafnium* (Köbenhavn, 1925) ; [3] and H. Rose in his *Das Hafnium* (Braunschweig, 1926).

After the discovery of hafnium, a controversy followed as to the priority of G. Urbain's[4] discovery—*vide* rare earths (**5.** 38, 25). G. Urbain claimed that he was the original discoverer of element 72, and that it should be called *celtium.* If the spirit of L. F. Svanberg were able to take part in the controversy, perhaps *norium* would be advocated ; if that of H. C. Sorby, *jargonium ;* if that of A. H. Church, *nigrum ;* and if those of K. A. Hoffmann and W. Prandtl, *euxenium.*

§ 2. The Occurrence of Hafnium

D. Coster and G. von Hevesy [1] found up to 30 per cent. of hafnium in the different zirconium minerals investigated. These minerals were from Norway, Greenland, Italy, France, Russia, Ceylon, Brazil, and North Carolina. At least 1 per cent. of hafnium was found in commercial zirconium preparations, and G. von Hevesy and V. T. Jantzen found typical thorium minerals—thorite, thorianite, and orangite—to be free from hafnium. Minerals like baddeleyite and

favas contain 1 to 2 per cent. of hafnium, while the most common silicates, and the zircons have between 1 and 7 per cent. The ratio $HfO_2 : ZrO_2$ was found to be appreciably greater in zirconium minerals than in less siliceous minerals. V. M. Goldschmidt and L. Thomassen found the richest hafnium content in the secondary minerals like *alvite*, regarded as *zirconium thorium hafnium orthosilicate*, $(Zr,Hf,Th)O_2.SiO_2$, and in *cyrtolite*, *nägeite*, and *malacone*. A specimen of the cyrtolite from Rockport, Mass., had 40 per cent. zirconium and 10 per cent. of hafnium. A. Piutti reported that Vesuvian zircon contains one per cent. of hafnium. E. and G. Urbain discussed the presence of both hafnium and the yttrium elements in some zirconium minerals, and found that the more hafnium is present the larger the proportion of rare earths. G. von Hevesy found that some historical preparations of zirconium from chemical museums contained 1 to 5 per cent. of hafnium. The relative amounts of the other members of the thorium family in the earth's crust, estimated by F. W. Clarke, and J. Joly, give silicon, Si, 27·7 per cent. ; titanium, Ti, 0·46 per cent. ; zirconium, Zr, 0·017 per cent. ; hafnium, Hf, over 0·002 per cent. ; and thorium, Th, 0·002 per cent.

§ 3. The Extraction of Hafnia

Hafnium is easily separated from the rare-earth elements ; and it was isolated by using methods employed for separating zirconium from thorium and titanium. According to G. von Hevesy and V. T. Jantzen, the mineral alvite was fused with ammonium hydrofluoride, and extracted repeatedly with boiling water, which dissolves very considerable amounts of ammonium fluosilicate, and zirconium,

hafnium, titanium, niobium, tantalum, vanadium, germanium, iron, and manganese, some of which are present only in very minute quantities. Thorium, the higher homologue of hafnium, and also the rare-earth elements present, remain insoluble, together with unattacked mineral and insoluble zirconium and hafnium fluoride compounds, such as sodium fluozirconate. Zirconium and hafnium can be separated by methods based on differences in the solubilities or vap. press. of corresponding compounds and partly on differences in their basicities. According to G. von Hevesy, the most practical method of separation is the crystallization of the double fluorides of potassium or ammonium. The mineral is melted with potassium hydrofluoride, and the hexafluozirconate extracted with boiling water, in which this compound is soluble to the extent of 25 per cent. On cooling, the greater part of the salt crystallizes out. G. von Hevesy and E. Madsen converted the product into the sulphate and then into the oxychloride, which is recrystallized, or treated with sulphur dioxide, which precipitates the hafnium and zirconium from the boiling soln., leaving most of the iron in soln. The double fluorides are best obtained by warming the dioxides with ammonium fluoride and hydrofluoric acid. The salt resulting from the fusion is unsuitable. The zirconium double fluoride being less soluble (2·6 per cent. at 20°) than the hafnium double fluoride (nearly 3 per cent. at 20°), the latter accumulates in the mother-liquor. Still more convenient is the crystallization of the highly soluble $(NH_4)_2ZrF_6$, soluble at 20° to the extent of 26 per cent. The ammonium double fluoride of hafnium crystallizes in prismatic (pseudo-hexagonal) crystals. The hafnium content is raised from 2 to 5 per cent. to 38 per cent. by fractionation of the ammonium compounds, and the subsequent fractionation of the potassium compounds furnishes a hafnium salt of 99·9 per cent. purity. The separation is controlled by X-ray spectroscopy and density determinations of the dioxides since the hafnia content x is obtained from the observed density D by $x=(D-5·73)/0·394$. M. Marquis and P. and G. Urbain separated hafnium from malacone by the following process :

Small quantities of the mineral can be decomposed by fusion with potassium hydrosulphate; with large quantities of material it is better to decompose with sulphuric acid although some of the mineral remains unaffected. The excess of acid is expelled by heat and the soluble sulphates are extracted, leaving silica. Solid potassium sulphate is added in excess to the concentrated soln. of sulphates to precipitate zirconium and hafnium as insoluble sulphates. The precipitate is washed with cold saturated potassium sulphate soln. Although the solubilities of the two double sulphates differ appreciably they are unsuitable for fractionation because they are hydrolyzed to basic salts in water and are only stable in strongly acid soln. Saturated sodium carbonate forms double carbonates with zirconium and hafnium, but when a mixture of salts is treated with sodium carbonate, zirconium is extracted first. Alkali precipitates zirconium before hafnium from simple salt mixtures, and hafnium before zirconium from mixtures of complex salts. A series of fractions of the double carbonates in order of increasing hafnium content is treated with the same amount of sodium hydroxide. In each fraction the ratio Hf/Zr is greater in the precipitate than in the mother-liquor. The precipitate is filtered off, dissolved in sulphuric acid, and neutralized until a cloudy precipitate persists ; this soln. is then added to the mother-liquor from the precipitate in the succeeding stage of the fractionation. In this way hafnium preparations can be obtained in which the strong spectrum lines of zirconium are only faintly observed.

Another suitable method of separation is the crystallization of the ammonium-zirconium oxalate. A soluble zirconium salt, like the sulphate, is precipitated with ammonia, the hydroxide dissolved in an excess of oxalic acid and neutralized with ammonia. By crystallizing the oxalate formed, hafnium accumulates in the mother-liquor. Crystallizing the oxychlorides from about 12N-HCl gives better results than the oxalate method. If the acid be less than 9N-HCl, no separation occurs. The hafnium accumulates in the crystals.

Less satisfactory is the result of the crystallization of the complex sulphate, like the ammonium salt of zirconium and sulphuric acid. The hafnium concentrates in the mother-liquor. To purify zirconium from iron and other impurities it can

be converted into the oxychloride. By repeatedly crystallizing this compound from hydrochloric acid pure zirconium is retained. Hafnium oxychloride is less soluble than zirconium oxychloride; thus while purifying zirconium from iron, its hafnium content is raised at the same time. For example, starting from 100 g. $ZrOCl_2$ containing 1 per cent. hafnium, the 30 g. oxychloride residue obtained after ten successive crystallizations contained a little over 2 per cent. of hafnium. Hafnium is more basic than zirconium, and accordingly, when precipitating a soln. of a zirconium salt with ammonia the first precipitate contains less hafnium than the successive ones. For example, when precipitating one-half of an oxychloride soln. containing 1 per cent. hafnium with dil. ammonia, the precipitate contains only 0·8 per cent., whilst the hafnium content of the soln. is increased to 1·2 per cent. This difference can be somewhat increased by the presence of large amounts of ammonium chloride in the soln. By boiling a soln. of zirconium and hafnium with sodium thiosulphate, zirconium being more strongly hydrolyzed, the first precipitate contains a larger amount of zirconium than the successive ones. From a soln. of zirconium sulphate, diluted about 1 : 40, a basic zirconium compound precipitates on standing a few days at 39·5°. Also with this process, like many similar ones, the precipitate contains slightly more zirconium than the soln. G. von Hevesy and V. T. Jantzen found that in the fractional crystallization it is better to work with ammonium fluozirconate and fluohafniate than with the potassium salts. The ammonium fluohafniate collects in the mother-liquor and the ammonium fluosilicate and fluozirconate with the crystals. When a mixture of hafnium and columbium double fluorides is heated carefully, and afterwards treated with boiling water and acid ammonium fluoride, only the hafnium salt dissolves. This enables columbium and hafnium to be separated. The precipitation as basic chloride; and with hydrogen dioxide; and organic acids—benzoic, salicylic, or tartaric acid—did not give good results. D. Coster and G. von Hevesy recommended precipitating the oxychlorides to separate iron, aluminium, etc. The mixture of hafnium and zirconium oxychlorides is dissolved in 50 parts by weight of alcohol and 125 parts by weight of ether are added. The zirconium concentrates in the precipitate, hafnium in the mother-liquor. Acetone may also be used as precipitant. Amongst all the precipitation methods, said G. von Hevesy, preference is to be given to the fractional precipitation by adding sodium phosphate to the soln. in conc. nitric acid. The eighth fraction contained less than one-tenth the amount of hafnium present in the first precipitate. J. H. de Boer and A. E. van Arkel found that the compounds of hafnium tetrachloride with phosphorus pentachloride and oxychloride are more volatile than is the case with the corresponding zirconium compounds, and hence hafnium concentrates in the earlier fractions. D. H. Drophy and W. P. Davey found that zirconium citrate is relatively insoluble in pure water, while hafnium citrate is quite soluble. Zirconium citrate is also soluble in ammonium hydroxide or in an excess of citric acid. By adding a limited amount of an aq. soln. of citric acid to a soln. of crude zirconium nitrate, a precipitate of pure zirconium citrate is obtained which was identified by its X-ray absorption spectrum. X-ray absorption spectra of the water-soluble citrate showed the presence of hafnium. The conditions of the separation are such that although the precipitate is free from hafnium the soluble portion contains some. zirconium. A number of methods of separating hafnium has been patented by the Naamlooze Vennootschap Gloeilampenfabrieken. This firm has also patented the use of hafnium nitrate admixed with tungstic oxide for making lamp filaments. The hafnium is supposed to prevent the recrystallization of the tungsten produced by reduction in hydrogen.

See § 2.

§ 4. Hafnium and its Properties

Metallic hafnium was prepared by reducing a hydrofluohafniate with sodium. A. E. van Arkel and J. H. de Boer made hafnium by passing the vapour of the tetraiodide over a heated tungsten filament—*vide* titanium ; and J. H. de Boer reduced the tetrachloride with sodium. The metal has the same crystal structure as zirconium, for, according to W. Noethling and J. Tolksdorf, it crystallizes in the hexagonal system, and the X-radiogram shows that the side of the unit triangular prism is 3·32 A., and the height, 5·46 A., so that the axial ratio $a : c = 1 : 1 \cdot 64$. The at. vol. is therefore 15·7. J. H. de Boer found the sp. gr. to be 12·1. A. E. van Arkel and J. H. de Boer found hafnium to be denser than zirconium, and also to possess a higher m.p. ; and a higher electron emission. According to S. Meyer, hafnium is diamagnetic.

D. Coster and G. von Hevesy measured the X-ray spectra of a number of zirconium minerals, and found some characteristic lines in the L-series belonging to no known element. The wave-lengths interpolated from the two elements before and after the element with the atomic number 72, correspond closely with the observed lines, namely, $a = 1565$; $a_2 = 1576$; $\beta = 1371$; $\beta_2 = 1350$; $\gamma = 1177$ X-units. A. Zacek found

				a_1	a_2	β_1	β_2	β_3
λ	.	.	.	1566·14	1576·70	1370·17	1349·1	1323·6
γ/R	.	.	.	24·122	24·041	25·789	25·990	26·239

where R denotes Rydberg's constant, and γ, the vibration frequency, the reciprocal of the wave-length. D. Coster examined the L-series of the X-ray spectrum. The X-ray method was employed for the quantitative determination of hafnium by using a known amount of the neighbouring element, 73—tantalum—and comparing the intensities of the lines of tantalum with those of the unknown element. H. M. Hansen and S. Werner measured 760 lines in the arc spectrum, and 683 in the spark spectrum of hafnium, and these all lie in the region 2253·95 A. and 7240·9 A. None of the lines ascribed to celtium was detected in the preparation of hafnium. Some of the weaker lines recorded by early investigation of zirconium really belong to hafnium, because the preparations all contained that element. J. Bardet also studied the arc spectrum. The X-ray spectra were examined by G. Urbain and A. Dauvillier, and B. B. Ray. D. Coster, and Y. Nishina measured the wave-lengths of the sixteen principal emission lines of the L-series, and two lines of the M-series. The K-absorption limit was also measured by D. Coster, and Y. Nishina, and the L-adsorption limit by M. de Broglie and J. Cabrera. The energy levels of the atoms of related elements have been computed.

See § 2.

§ 5. The Salts of Hafnium

The chemical properties of hafnium come between those of zirconium and thorium, but are much nearer those of zirconium. Any reaction characteristic of zirconium is also characteristic of hafnium. F. Steidler compared reactions with purified zirconium and purified hafnium—precipitation with potassium oxalate, rubidium chloride, ammonium fluoride, picric acid, and a-nitroso-β-naphthol— but not the slightest difference could be detected. The high m.p. and light emissivity of zirconia are shared by hafnia—**hafnium dioxide,** HfO_2 ; and the electronic emission of the heated metal exhibited by zirconium is also shown by

hafnium and its compounds. G. von Hevesy and V. Berglund prepared the oxide by igniting the sulphate at 1000°. The sp. gr. at 20° is 9·68 when that of zirconia is 5·73. The oxides prepared from the basic sulphate or oxychlorides are 0·2 lower. The hafnia content, x, of zirconia can be found with a fair degree of accuracy from the sp. gr. of the oxides prepared from the normal sulphate by $x=(D-5·731)/0·0394$. The mol. vol. of hafnia is 21·76, that of zirconia 21·50. Contrasting the sp. gr. and mol. vol. of some related oxides :

	TiO_2	ZrO_2	HfO_2	ThO_2
Specific gravity . . .	4·26	5·73	9·68	10·22
Molecular volume . .	18·8	21·5	21·7	25·8

F. Henning gave 2812° for the estimated m.p. of the dioxide. The magnetic susceptibility of hafnia found by G. von Hevesy is $-0·110 \times 10^{-6}$ units per gram, so that the oxide is diamagnetic. The solubilities of some hafnium compounds are greater than those of zirconium and thorium ; thus, the solubility of **ammonium hexafluohafniate**, $(NH_4)_2HfF_6$, is greater than that of the corresponding fluothoriate, or fluozirconate. G. von Hevesy and co-workers found the solubility of ammonium hexafluohafniate, $(NH_4)_2HfF_6$, in water to be at 0°, 1·807 mol and 0·890 mol respectively of NH_3 and Hf per litre ; and at 20°, 28·32 mol and 1·425 mol respectively ; and of **ammonium heptafluohafniate**, $(NH_4)_3HfF_7$, at 0°, 1·230 mol and 0·425 mol respectively of NH_3 and Hf per litre, and at 20° respectively 1·756 and 0·588. For the solubility of ammonium heptafluohafniate in ammonium fluoride at 20° :

Mol of NH_4F per litre . .	0	0·992	1·971	5·01
Mol Hf per litre . . .	0·588	0·261	0·1080	0·0258

The effect of temp. on the solubilities of the two ammonium fluohafniates is indicated in Fig. 1, along with the solubilities for the corresponding zirconium salts ;
FIG. 1.—Effect of Temperature on the Solubilities of the Ammonium Fluozirconates and Fluohafniates.
FIG. 2.—Effect of Ammonium Fluoride on the Solubilities of Ammonium Heptafluozirconate and Heptafluohafniate.

·and the effect of increasing the conc. of the ammonium fluoride on the solubilities of the heptafluohafniates and the heptafluozirconates at 20° is shown in Fig. 2. The mutual solubility of the hexa- and hepta-fluohafniates in water at 20° is illustrated by Fig. 3. The solid phases are indicated in the diagram. The solubility of **potassium hexafluohafniate**, K_2HfF_6, in 0·125N-HF and 5·89N-HF is respectively 1·008 and 1·942 mol per litre at 20°. Comparing the solubilities of the family group in 0·125N-HF at 20° excepting the value for K_2SiF_6 which refers to water at 17·5° :

	K_2SiF_6	K_2TiF_6	K_2ZrF_6	K_2HfF_6	K_2ThF_6
Solubility . .	0·00544	0·0483	0·0655	0·1008	Insoluble

The X-radiogram of ammonium heptafluohafniate by O. Hassel and H. Mark indicates that the elementary cubic cell has a side of 9·40 A., and contains 4 mols.

The mol. vol. is 125·7, and that of the corresponding zirconium salt, 123·9. G. von Hevesy gave 1·461 for the maximum and 1·449 for the minimum refractive index of the monoclinic crystals of potassium hexafluohafniate; 1·403 for the octahedral crystals of potassium heptafluohafniate; and 1·426 for those of ammonium heptafluohafniate. Like zirconium tetra-chloride, **hafnium tetrachloride** volatilizes appreciably at 250°, and the first distillate contains rather more zirconium than the original mixture; **hafnyl chloride,** $HfOCl_2$, is less soluble than the corresponding zirconyl chloride, $ZrOCl_2$; **hafnium iodide,** HfI_4, was prepared by J. H. de Boer. If ether be added to an alcoholic soln. of hafnyl chloride, a higher basic **hafnium oxychloride,** $Hf_2O_3Cl_2.5H_2O$, is formed less soluble than the corre-sponding zirconium compound, and the fact can be used in purifying conc. hafnium preparations from zir-conium. As the conc. of the acid increases, the solubility first rapidly and later slowly decreases; but after the conc. of about 9 mol per litre is attained an increase of the solubility with increasing acid conc. begins. This increase of the solubility is possibly due to the formation of complex compounds such as H_2ZrOCl_4 and H_2HfOCl_4.

FIG. 3.—Mutual Solubili-ties of Ammonium Hexa- and Heptafluo-hafniates.

It is of interest to note that while the solubility of the hafnium salt is practically the same as that of the zir-conium salt in hydrochloric acid when the conc. of the latter does not exceed 9 mol per litre, it is appreciably less soluble in more concentrated hydrochloric acid. The solubility of hafnium oxychloride in still more concentrated acid (11·4N) is less, namely, 0·0619. G. von Hevesy gave $\omega=1·557$ and $\epsilon=1·543$ for the refractive indices of the tetragonal crystals of octohydrated hafnium oxy-chloride. A. E. van Arkel and J. H. de Boer made **hafnium sulphide** by passing the vapours of the tetrachloride and sulphur over a heated tungsten filament. **Hafnyl hydrophosphate,** $HfO(HPO_4)_2$, is the least soluble of all the known phos-phates; it resembles the corresponding zirconium salt very closely. A. E. van Arkel and J. H. de Boer found that the soln. of hafnium hydrophosphate behave like those of the zirconium salt but they are less stable, and this enables a separation of hafnium and zir-conium to be made. According to E. von Hevesy and K. Kimura, **hafnyl dihydrophosphate,** $HfO(H_2PO_4)_2$, is precipitated from 6N-HCl; and the solubility in 6N-HCl and 10N-HCl is respec-tively 0·00009 and 0·00012 mol per litre. The salt loses 2 mols of water when ignited, forming **hafnyl metaphosphate,** $HfO(PO_3)_2$. The pro-gress of the reaction $HfO(H_2PO_4)_2 \rightarrow HfO(PO_3)_2$ at different temp. is illustrated by Fig. 7—7. 42,

FIG. 4.—The Effect of Hydrochloric Acid on the Solubilities of Zirco-nium and Hafnium Oxychlorides.

15. According to G. von Hevesy, **hafnium salicylate** is less soluble than zir-conium salicylate; **hafnium oxalate** is soluble in an excess of oxalic acid. Hafnium is more basic than zirconium, so that the latter is more easily precipi-tated by ammonia, sodium thiosulphate, etc. Zirconium sulphate begins to decompose at about 400°, **hafnium sulphate,** $Hf(SO_4)_2$, at about 500°.

The **atomic weight** given by D. Coster is between 174 and 180. T. E. Thorpe suggested that the discrepancy in the at. wt. determinations of titanium is pro-bably due to the presence of an element of this character and with a high at. wt. O. Hönigschmid and E. Zintl determined the at. wt. of hafnium by the analysis of the bromide containing about 6 per cent. of zirconium and obtained 171·88,

which, when corrected for the zirconium content by G. Hevesy, became 178·6. The presence of 1 per cent. zirconia lowers the at. wt. of hafnium 1·4 units.

According to N. Bohr's theory of the electronic structure corresponding with the number of electrons in the different groups of the neutralized atom of titanium, zirconium, hafnium, and thorium are :

Ti   .   .   .   (2) (4,4) (4,4,2) (2)
Zr   .   .   .   (2) (4,4) (6,6,6) (4,4,2) (2)
Hf   .   .   .   (2) (4,4) (6,6,6) (8,8,8,8) (4,4,2) (2)
Th   .   .   .   (2) (4,4) (6,6,6) (8,8,8,8) (6,6,6) (4,4,2) (2)

CHAPTER XLIV

THORIUM

§ 1. The History and Occurrence of Thorium

IN 1815, J. J. Berzelius [1] obtained from a mineral from Finbo near Fahlun what he regarded as a new earth resembling zirconia. This earth was named *thorine* after the god Thor of Scandinavian mythology. In 1824, he showed that thorine was essentially yttrium phosphate. Four years later, J. J. Berzelius discovered another earth in a new mineral from Lövö near Brevig in Norway. He found this earth to be *sui generis*, distinct from all others, and he applied to the earth the old name *thoria* or *thorina*. The mineral in which the earth was discovered was named *thorite*.

C. Bergemann,[2] reported the discovery of a new earth in orangite, from Langesund fiord, Norway, and he named the element *donarium ;* but A. Damour, and N. J. Berlind identified donaria with thoria. J. F. Bahr [3] also reported a new earth in orthite ; and he named the element *wasmium.* J. Nicklès regarded wasmium as a didymiferous and terbiniferous yttria ; M. Delafontaine suggested that it is a mixture of cerite earth : O. Popp made a similar suggestion ; and J. F. Bahr himself later identified it with thoria —*vide* rare earths for *berzelium,* and *carolinium.*

Thorium is widely distributed in nature, but in very small proportions. J. Joly [4] estimates that the earth's lithosphere contains from 0.2×10^{-5} to 3×10^{-5} grm. per gram. F. W. Clarke's and J. Joly's estimates indicate that 27·7 per cent. of the earth's crust is silicon ; 0·46 per cent. titanium ; 0·017 per cent. zirconium ; and 0·002 per cent. thorium. J. H. L. Vogt estimated that the ten-mile crust, the hydrosphere, and lithosphere of the earth contained $n \times 10^{-9}$ per cent. of thorium ; and F. W. Clarke and H. S. Washington, $n \times 10^{-8}$ per cent. Frequently thorium and uranium occur in approximately the same proportions— *vide* radioactivity of thorium. Thorium occurs in Vesuvian lava ; T. L. Phipson found it in Norwegian granites ; A. L. Fletcher, in Leinster granites ; G. A. Blanc found in the syenites and granites of Vosges, 2×10^{-5} to 8×10^{-5} grm. of thorium per gram ; and 0·00145 per cent. of thorium in the soils near Rome ; J. Joly found 0.1×10^{-5} grm. of thorium per gram in limestones and dolomites ; 0.54×10^{-5} grm. per gram in sandstones from different localities ; and 1.14×10^{-5} in a number of argillaceous rocks. H. Lange found thoria is contained in fluorspar ; and, according to R. J. Strutt, a sample of Greenland fluorite contained 18.2×10^{-3} per cent. of thoria. J. Joly estimates that sea-water contains about 10^{-8} grm. of thorium per c.c. The occurrence of thorium in atm. air, spring waters, etc., is discussed in connection with thorium emanation (*q.v.*).

H. A. Rowland could not detect any thorium lines in the solar spectrum although G. Hofbauer gives a number of these lines. Thorium occurs associated in small quantities with the rare earths in most of the minerals discussed in connection with the rare earths ; and also with many tantalum, columbium, titanium, scandium, zirconium, and uranium minerals. The thorium minerals are largely conc. in about five districts: (i) Norway and Sweden—*e.g.* Arendal, Kragerö, Brevig, Hitterö Langesund, Bastnaes, Ytterby, etc. (ii) North America—*e.g.* North and South

Carolina at Burke, Cleveland, MacDowell, Spartanburg, etc. ; in Llano County, Texas, Idaho at Idaho City, Placerville, Boisé City, etc. ; in Virginia, and Colorado. (iii) Brazil—*e.g.* Bahia, Caravellas, Matto-Grosso, Goyaz, Minas Geraes, etc. (iv) Urals—*e.g.* Miask, etc.   (v) Tasmania—*e.g.* Vegetable Creek, etc. Specimens have been reported from Scotland, Saxony, Ceylon, and Greenland. The dark brown or black mineral **thorite** was discovered on the island Lövö, in the fiord Langesund, Norway, in 1828 by H. M. T. Esmark,[5] and it was analyzed by J. J. Berzelius. In 1850, A. Krautz found the yellow mineral **orangite** which was analyzed by C. Bergemann, and named in allusion to its colour. For a time, these minerals were considered to be different species. In 1859, T. Scheerer argued that orangite and thorite are chemically and crystallographically similar, and that thorite is a transformation product of orangite. This view was supported by J. J. Chydenius, A. Breithaupt, A. E. Nordenskjöld, etc. Analyses have been made by J. J. Berzelius (1), C. Bergemann (2), A. Damour (3), N. J. Berlin, J. J. Chydenius, G. Lindström, W. E. Hidden and J. B. Mackintosh, L. Schilling (4, 10), P. G. Tschernik (5), W. R. Dunstan (6), P. Collier (7), A. E. Nordenskjöld (8), G. Lindström (9), etc.

TABLE I.—ANALYSES OF ORANGITE AND THORITE.

Source.	SiO_2	ThO_2	U_2O_3	PbO	Fe_2O_3	CaO	H_2O
1. Lövö, Norway .	19·31	58·91	1·64	0·82	3·46	2·62	9·66
2. Brevig, Norway .	17·69	71·25	—	—	0·31	2·24	6·90
3. Brevig, Norway .	17·52	71·65	1·13	0·88	0·31	1·59	6·14
4. Arendal, Norway .	17·62	69·92	1·09	—	1·23	1·07	7·01
5. Batum, Asia Minor .	16·55	68·71	1·20	0·90	0·30	2·30	6·43
6. Kondrugala, Ceylon .	14·10	66·26	0·46	—	1·71	0·35	6·40
7. Champlain, N.Y. .	19·38	52·07	9·96	0·40	4·01	2·34	11·31
8. Arendal, Norway .	17·04	50·06	9·78	1·67	7·60	1·99	9·46
9. Arendal, Norway .	17·47	48·66	9·00	1·26	6·59	1·39	10·88
10. Brevig, Norway .	17·00	50·05	9·67	0·36	7·82	0·36	11·95

P. Truchot found 50–58 per cent. of thoria in thorite, and 71·65 per cent. in orangite ; L. Schmelck, 50 per cent. in thorite, and 70 per cent. in orangite ; G. P. Drossbach, 20–40 per cent. in thorite ; W. R. Dunstan, 66·26 per cent. ; B. Szilard, 42·5 per cent. ; etc.   J. Schilling found 69·92–74·20 per cent. in orangite ; N. J. Berlin, 73·29 per cent. ; A. Damour, 71–74 per cent. ; J. J. Chydenius, 73·80 per cent. ; etc.   In addition to these constituents, the manganese oxide ranged up to 2·43 ; the alumina up to 0·84 ; the alkalies up to 0·82 ; magnesia up to 0·36 ; the stannic oxide up to 0·01 ; the phosphoric oxide up to 1·20 ; the ceria earths up to 1·54 ; the yttria earths up to 1·33 ; and the Cingalese sample had 2·23 per cent. of zirconia. G. von Hevesy and V. T. Jantzen reported no evidence of hafnium (or celtium) in thorite or orangite. The thoria in C. Bergemann's analysis was reported as donaria. E. Gleditsch found 0·0033 per cent. of lithium in thorite. Specimens (7–10) with the higher proportions of uranium oxide were called by P. Collier **uranothorite.** The results show that thorite is probably analogous with zircon, cassiterite, and rutile, and is an impure thorium orthosilicate, $ThSiO_4$, or $ThO_2.SiO_2$—*vide* zircon.

The specimens here analyzed contain water, showing that they are more or less weathered. A. Breithaupt, and A. E. Nordenskjöld consider thorite to be more impure than orangite. According to L. F. Nilson, the uranium is present as UO_2, and this agrees with C. W. Blomstrand's observations on the occurrence of the uranates. C. F. Rammelsberg wrote the formula (SiO_2, ThO_2), H_2O, or $3(SiO_2, ThO_2)$, $4H_2O$; F. Zambonini gave for thorite $(SiO_2, ThO_2), nH_2O$, where n ranges from 1·0–1·5 ; and for uranothorite, $(SiO_2,ThO_2.UO_2).nH_2O$, where n is greater than 1·5. The mineral occurs as pseudomorphs after orthoclase and zircon ; and E. Zschau found the mineral to be tetragonal with the axial ratio $a : c = 1 : 0.642$,

and isomorphous with zircon, rutile, and cassiterite—and probably also with naegite, and xenotime ; and, according to G. T. Prior, and W. T. Schaller, with ilmenorutile, strüverite, as well as with tapiolite or mossite. W. F. Hillebrand synthesized crystals resembling thorite by fusing uranium dioxide, UO_2, and thorium dioxide, ThO_2, with borax. L. Vegard obtained no evidence of crystalline structure in the X-radiogram of thorite ; the sample used was presumably altered or weathered. M. L. Huggins found the structure to be like that of rutile and other tetragonal crystals. As a rule, with many exceptions, isomorphous compounds have mol. vols. of nearly equal value. Thorite (orangite), however, does not fit in with the series :

	Cassiterite $Sn(SnO_4)$	Rutile $Ti(TiO_4)$	Zircon $ZrSiO_4$	Thorite $ThSiO_4$	Xenotime YPO_4
Mol. vol.	44	38	39	60	41

Just as the proportion of water in thorite varies from specimen to specimen, so does the sp. gr. alter. J. J. Berzelius gave 4·8 ; J. J. Chydenius, 4·888–5·205 ; P. G. Tschernik, 3·36 ; W. R. Dunstan, 4·98 ; A. E. Nordenskjöld, 4·38 ; W. E. Hidden and J. B. Mackintosh, 4·322 ; A. Damour, 5·19 ; G. Lindström, 4·62–4·80 ; W. C. Brögger, 4·114 ; and P. Collier, 4·126. The values for orangite are usually greater than for thorite, being 4·4–4·8 for thorite, and 5·2–5·4 for orangite. The hardness ranges from 4·5–5·0 ; A. L. Fletcher gave 1255°–1270° for the m.p. of the mineral. F. Beijerinck said that thorite is a non-conductor of electricity. The radioactivity has been discussed by F. Pisani, F. Kolbeck and P. Uhlich, A. E. Nordenskjöld, R. J. Strutt, V. Goldschmidt, E. Gleditsch, G. F. Barker, B. B. Boltwood, H. M. Dadourian, H. N. McCoy and W. H. Ross, K. A. Hofmann and F. Zerban, etc. ; for the occurrence of helium in the mineral by W. Ramsay and co-workers, R. J. Strutt, etc.—vide the radioactivity of thorium. J. N. Lockyer reported some unknown lines in the spectrum of the mineral. O. Mann regards thorite as the decomposition product of a thorium phosphate analogous to monazite. R. J. Strutt estimated the age of thorite from the helium content—vide radioactivity of thorium. According to C. R. Böhm, the transformation or weathering of thorite furnishes auerlite, thorogummite, calciothorite, mackintoshite, eucrasite, and freyalite.

The jet-black pseudocubic crystals occurring in the river-gravels or gem-gravels of Ceylon were once regarded as pitchblende, but the analyses of W. R. Dunstan [6] and co-workers showed that the crystals consist of 55–79 per cent. of thoria associated with 11–32 per cent. of uranium oxide, and 1–8 per cent. of oxides of the ceria earths, with smaller quantities of lead and iron oxides, zirconia, and silica. The mineral was named **thorianite.** Analyses have been reported by W. Ramsay, W. R. Dunstan and co-workers (3, 4), M. Ogawa (1, 2), P. Termier, R. J. Strutt, A. K. Coomaraswamy, T. L. Phipson, W. Jakob and J. S. Tolloczko, etc.

	SiO_2	TiO_2	ZrO_2	ThO_2	U_3O_8	$(Ce,La,Di)_2O_3$	PhO	Al_2O_3	Fe_2O_7
1 . . .	0·20	–	0·09	78·00	14·54	1·41	2·66	0·15	1.54
2 . . .	0·20	0·88	0·15	58·27	33·27	1·05	3·80	0·03	1·83
3 . . .	—	—	—	72·24	11·19	6·90	2·25	—	1·92
4 . . .	—	—	—	78·86	15·10	1·02	2·59	—	0·40

Other constituents are present. G. von Hevesy and V. T. Jantzen found no hafnia in the mineral. M. Ogawa gave 0·02–0·03 of CuO ; 0·05, SnO_2 ; 0·11, Sb_2O_3 ; 0·10–0·27, CO_2 ; 0·60–3·20, H_2O ; and 0·13–1·13, CaO. A. Schoep has argued that the formula of thorianite is ThO_2 ; that that of uraninite is UO_2 ; and that these two minerals occur in isomorphous association. M. Kobayashi assumes that there are two varieties : α-thorianite with the ratio ThO_2 ; U_2O_3 =6 : 1 ; and β-thorianite with this ratio 2 : 1, and he explains the divergencies in the analytical results by assuming that mixtures of the two varieties have been analyzed. The helium content has been determined by W. Ramsay. R. J. Strutt, D. O. Wood, etc. ; the radioactivity by E. Gleditsch, H. Goldschmidt, F. Soddy

and R. Pirret, A. K. Coomaraswamy, etc. From the helium content, E. Rutherford estimated the age to be at least 4×10^8 yrs.—*vide* the radioactivity of thorium.

E. H. Buchnen reported that thorianite contained a new element in the analytical arsenic group, and two in the bismuth-cadmium group ; C. de B. Evans, that it contained an element in the tin group ; and M. Ogawa, that thorianite and molybdenite contained a new element closely allied to molybdenum, and which he called *nipponium*, Np. This has not yet been confirmed. G. G. Boucher observed in certain specimens of iron and steel a metal resembling molybdenum in some respects but different from it in others. F. G. Ruddock, and C. H. Jones made some observations on this subject ; and A. Skrabal and P. Artmann noted a similar metal in ferrovanadium.

W. R. Dunstan and co-workers assume that thorium and uranium dioxides are isomorphous so that thorianite is a solid soln. of the two oxides ThO_2 and UO_2. The constitution was discussed by G. Wyrouboff and A. Verneuil. G. Troost and L. Ouvrard obtained octahedral crystals of thoria, and W. F. Hillebrand octahedral crystals of uranous oxide belonging to the cubic system, whereas the crystals of thorianite belong to the rhombohedral system. On the other hand, J. Nordenksjöld, C. F. Rammelsberg, and W. F. Hillebrand obtained octahedral crystals of thorianite by fusing the two oxides with borax. The sulphates of uranium and thorium were shown by C. F. Rammelsberg, and W. F. Hillebrand and W. H. Melville, to be isomorphous. It is therefore inferred that the two oxides are probably isomorphous. B. Szilard also assumes that uranium and thorium oxides form solid soln. The twinning of the pseudocubic crystals of thorianite resembles that of fluorspar ; but, like the zeolite chabazite, the optical properties correspond with the symmetry of the rhombohedral system, and the angles are probably very close to those of the cube. In view of the fact that both uranous oxide and thoria form octahedral crystals, while a fused mixture of the two yields, on cooling, cubic crystals, it is possible, but not proved, that the pseudocubic thorianite becomes truly cubic at high temp. The values for the sp. gr. of thorianite reported by W. R. Dunstan and co-workers range from 8·0–9·7 ; the hardness is 7 ; the index of refraction, 1·8. C. Baskerville found that thorianite is decomposed when heated in a stream of carbonyl chloride.

§ 2. The Extraction of Thoria

J. J. Berzelius,[1] the discoverer of this earth, extracted it from thorite. The powdered mineral was warmed with hydrochloric acid; some chlorine was evolved, and the mineral gelatinized. The whole was evaporated to dryness to make the silica insoluble. The residue was leached with dil. hydrochloric acid, and the lead, tin, etc., removed from the filtered soln. by hydrogen sulphide. The filtrate was treated with ammonia, and the washed precipitate dissolved in dil. sulphuric acid. The soln. was evaporated at a gentle heat, when thorium sulphate was deposited as a salt sparingly soluble in the hot liquid. The supernatant liquid was poured off, the crystals dried by press. and ignited for thoria. The mother-liquor was

conc. by evap., neutralized with potassium carbonate, and mixed with a boiling sat. soln. of potassium sulphate. The double sulphate which separates on cooling was washed with a sat. soln. of potassium sulphate; dissolved in water; and thorium hydroxide precipitated by ammonia. The presence of manganese imparted a yellow colour to the ignited mass; and J. J. Berzelius found it better to repeat the treatment with sulphuric acid rather than separate the thorium as oxalate. J. J. Chydenius used a similar process.

L. Troost heated a mixture of thorite with finely powdered coal in the electric arc furnace. All but about 1·5 per cent. of silica is volatilized, and this is said to facilitate greatly the subsequent treatment for thoria. O. N. Witt dissolved the washed precipitate in hydrochloric acid. Oxalic acid was then added so long as precipitation occurred. The washed precipitate was calcined. A little uranium, manganese, and rare earths were contained in the resulting thoria. J. J. Berzelius' process is based on the sparing solubility of thorium sulphate in comparison with the sulphates of the other earths. Modifications were suggested by M. Delafontaine, P. T. Cleve, L. F. Nilson and co-workers. J. J. Berzelius, and J. J. Chydenius also, purified the thoria by a process based on the sparing solubility of the double salt—potassium thorium sulphate—in a sat. soln. of potassium sulphate. The yttria earth sulphates are fairly soluble and are readily removed. Processes for the removal of the ceria earths based on the solubility of thorium oxalate in ammonium oxalate or ammonium carbonate, under conditions where the other oxalates are but sparingly soluble, have been given by A. Damour, R. Bunsen, H. Moissan and A. Étard, P. Jannasch and co-workers, J. Lesinsky, and G. Urbain. Vide the rare earths. V. I. Spitzin has measured the solubility of thorium oxalate in various soln.

J. J. Chydenius extracted thoria from euxenite by digesting the powdered mineral with conc. sulphuric acid; the product was dissolved in cold water and the soln. boiled for some days. The greater part of the titanium and columbium was precipitated. The thoria was then extracted from the filtrate by J. J. Berzelius' process. J. L. Smith extracted the thoria from samarskite by digesting the powdered mineral with cold conc. hydrofluoric acid, finishing off the operation by warming the mass. The rare earth fluorides, thorium fluoride, and uranium fluoride remain undissolved; the columbium, tantalum, iron, and manganese pass into soln. The insoluble mass is digested with sulphuric acid, and the soln. then treated for thoria by the oxalate process. G. Siebert and E. Korten treated the raw material with halogens in the presence of carbon at a high temp.

According to C. R. Böhm, most of the thorium compounds in commerce are extracted from monazite sand as described in connection with the rare earths. The deposits in the vicinity of Bahia, Espirito Santo, and Rio de Janeiro on the Brazilian coast, have been worked for many years. The deposits in North and South Carolina in the United States, and the deposits at Travancore, Southern India, are also worked. The monazite sands contain 2–60 per cent. of monazite. The monazite from Brazil contains 5–6 per cent. of thoria, while, according to E. White, Travancore monazite has 6–14 per cent. of thoria. The grains of monazite in the sand are associated with quartz, ilmenite, garnet, rutile, zircon, hornblende, etc. The sand is usually conc. until it contains at least 90 per cent. monazite.

The concentration of monazite sand has been discussed by H. B. C. Nitze, F. Freize, etc. In the wet process of extraction the sand is run with a stream of water on to one corner of a rectangular table. The table is so tilted that the material travels diagonally across it; the passage of the particles across the table is assisted by the shaking or jigging motion mechanically imparted to the table. The particles roughly range themselves in the order of their sp. gr. The weakness of the process is the tendency for aggregates of small particles of high sp. gr. to behave like a smaller number of large particles of small sp. gr. Pneumatic processes can be used in which blasts of air take the place of currents of water. The initial concentration may be performed by a wet process, and the conc. then

raised by electro-magnetic separation. Electro-magnetic separation is considered to be the most satisfactory method of obtaining a high-grade monazite. In this process, a belt, B_1, Fig. 1, carries the well-dried sand from a hopper, H, and projects it against a second belt, B_2, which travels just beneath the poles, P, P, P, of a powerful electro-magnet. The constituent minerals of the sand are attracted towards the magnet in varying degrees and fall into collecting boxes, A, B, arranged in the order of their magnetic permeability. The non-magnetic discharge collects in the box C. Two repetitions of the process will usually give

FIG. 1.—Magnetic Concentration of Monazite Sand (Diagrammatic).

a concentrate with 90–95 per cent. of monazite. The subject is discussed in C. G. Gunther's *Electromagnetic Ore Separation* (New York, 1909), and D. Korda's *La séparation électromagnétique et électrostatique des minerais* (Paris, 1905).

C. R. Böhm thus outlines the process employed for extracting thorium from monazite concentrates. The conc. monazite may or may not require a preliminary grinding. It is then mixed with about twice its weight of conc. sulphuric acid (sp. gr. 1·84), and heated in cast-iron pans until the white pasty mass of sulphates, etc., is soluble in water, and no yellow grains of monazite remain undissolved. The product is then run into a leaden vat and the whole is well stirred. The mixture is allowed to stand in order to allow the insoluble or unattacked minerals to settle. The soln. containing the rare-earth phosphates is syphoned off. The ratio of thoria to the rare earths in the soln. is about 1 : 12. Thorium is more basic than the rare earths, so that when the acid soln. is gradually neutralized by adding ammonia, alkali hydroxide or carbonates, or, more usually, magnesite, thorium phosphate accumulates in the first precipitate. The thorium phosphate is filtered off, dissolved in the minimum quantity of acid, and the process repeated. This raises the proportion of thoria to the rare earths to about 4 : 1. The product is next to be freed from phosphoric acid and the remaining ceria earths.

Several processes have been suggested ; but many of them are too expensive for commercial work. The actual procedure is kept a secret. In the oxalate process described by C. R. Böhm, the acid soln. of the phosphate is treated with a hot soln. of oxalic acid ; the precipitated oxalates are washed, digested with a soln. of sodium carbonate, as recommended by O. N. Witt, and precipitated from the soln. with sodium hydroxide ; or the mixed oxalates are treated with a warm soln. of ammonium oxalate, as recommended by R. Bunsen, when all the thorium oxalate dissolves and only small quantities of the other oxalates pass into soln., and these are nearly all precipitated when the soln. is diluted. O. N. Witt recommends applying the sodium thiosulphate precipitation—*vide infra*—before the oxalate treatment. The Société Minière et Industrie Franco-Brésilienne precipitated the thorium, cerium, etc., as anhydrous sulphates from the sulphuric acid soln. of monazite, and removed the phosphoric acid by centrifuging. M. Fronstein and J. Mai, J. W. Ling, G. Thesen, H. Moissan and A. Étard, G. Urbain, etc., used modifications of the oxalate process.

B. Kossmann treated the sulphuric acid soln. of monazite with ammonia ; dissolved the precipitate in hydrochloric acid; sat. the feebly acid soln. with hydrogen sulphide ; decanted the clear liquid from the precipitated aluminium and iron phosphates and tin sulphide, and treated the soln. with hydrogen dioxide, ammonia, and ammonium citrate. The precipitate contained aluminium phosphate mixed with thorium hydroxide—freed from didymium and cerium compounds. The precipitate was dissolved in nitric acid, and the thorium purified by the oxalate process, or by the acetate process. In F. Haber's form of the acetate process,

the impure hydroxide is dissolved in acid, and the thorium precipitated from neutral soln. by sodium acetate. The treatment is repeated until the purification has been carried far enough. The results are said to be good, but too costly for large-scale work.

G. Wyrouboff and A. Verneuil recommend the following process :

The mineral is dissolved in the usual way, and the soln., which must contain sufficient acid to prevent precipitation of the phosphates, is precipitated with half the quantity of oxalic acid necessary for complete precipitation. The oxalates are washed until free from phosphoric acid, converted into carbonates by means of a hot soln. of sodium carbonate (1 : 10), and some sodium hydroxide added to ensure complete precipitation of the thorium. The carbonates are washed until free from oxalic acid, dissolved in just the necessary quantity of hydrochloric acid, and mixed with successive small quantities of barium peroxide suspended in water until the liquid gives no precipitate with hydrogen dioxide. The precipitated peroxide contains all the thorium, together with 20-30 per cent. of impurities ; it is washed and dissolved in cold conc. hydrochloric acid, barium eliminated by means of sulphuric acid, enough water added to yield a soln. containing 15 per cent. of acid, and the bases precipitated with oxalic acid. The oxalates are washed, and treated with a highly conc. soln. of ammonium carbonate mixed with sufficient ammonia to form the normal salt. By two or three successive treatments, all the thorium is dissolved, and the soln. is precipitated by means of sodium hydroxide, the precipitate well washed and dissolved in not more than the requisite quantity of nitric acid, and the liquid poured into sufficient water to yield a soln. containing not more than 2 per cent. of thorium. Excess of hydrogen dioxide is then added, and the precipitate is well washed. From this point, all the reagents must be pure. The precipitate is dissolved in nitric acid and re-precipitated with hydrogen dioxide in order to eliminate all the cerium. It is next dissolved in hydrochloric acid, precipitated with oxalic acid, and the oxalate decomposed by pure sodium hydroxide. After careful washing, the precipitate is again dissolved in hydrochloric acid and precipitated with ammonia. This final precipitate is well washed, dissolved in nitric acid, and the nitrate crystallized.

C. R. Böhm removed the phosphates by fusing the precipitate with sodium carbonate and leaching the mass with water. The phosphates and silicates pass into soln., while the thoria and rare earth oxides remain. W. Buddёus and L. Preussner used alkali hydroxides in place of the carbonate. L. Weiss heated a mixture of monazite with carbon in an electric furnace whereby carbides and phosphides are formed. The mass was treated with hydrochloric acid, and the phosphorus escaped as phosphine. C. Baskerville proposed to volatilize the phosphorus by heating a mixture of monazite, coke, calcium oxide, and fluorspar in an electric furnace until the fumes of phosphorus were no longer evolved. When the cold mass is treated with water, acetylene is evolved. The powder is well washed to remove the lime, and then dissolved in hydrochloric acid for the separation of thorium, etc.

The purification of thoria.—The thoria contains a little sulphate, phosphate, calcium oxide, alkalies, zirconia, and rare earths. The usual methods of purification are (i) the fractional crystallization of the sulphates; (ii) the fractional soln. of the oxalates; or (iii) the separation by double alkali carbonates. There are also a number of processes more or less adapted for special purposes, but which are usually too expensive for large-scale operations. These processes have been discussed in a special section dealing with the separation of the rare earths. The oxalate process is based on the property possessed by thorium oxalate of forming a soluble double salt with ammonium oxalate, while the cerium earth oxalates are but sparingly soluble in that medium. The relative solubilities of the various oxalates are :

Th	Yb	Y	Ce	Nd	Pr	La
2663·0	105·0	11·0	1·8	1·5	1·2	1·0

The method—*vide supra*—was employed by B. Brauner, C. Böttinger, P. Jannasch and co-workers, C. Winkler, J. Lesinsky, E. Rimbach and A. Schubert, etc.

The sulphate process is based upon the property which thorium possesses of forming a number of hydrated sulphates, some of which differ so much in solubility from the ceria earths that a separation can be readily obtained. The process was

employed by L. F. Nilson, G. Krüss, P. T. Cleve, O. N. Witt, I. Koppel and H. Holt-kamp, etc. G. Thesen fractionally crystallized the double sodium sulphates. C. Baskerville employed the following process:

> The sulphate was taken up in cold water, treated with sodium sulphate and allowed to stand from twelve to twenty-four hours to insure separation of the remaining cerium salts, the percentage of which was quite small. The liquid was filtered and the hydroxide precipitated in tall cylinders by a large excess of purified sodium nitrate. This precipitate was washed by decantation from six to ten times, using each time 20 vols. of water to one of the precipitate. To remove the last of the sodium salts and other soluble impurities the precipitate was then dissolved in hydrochloric acid, reprecipitated by a slight excess of ammonium hydroxide and washed by decantation at least ten times, using 20 vols. of distilled water.

H. Erdmann used a modification of this process. The ammonium carbonate process of A. Damour is based on the solubility of thorium carbonate in a soln. of ammonium carbonate under conditions where only small proportions of the other carbonates are soluble.

L. M. Dennis and co-workers precipitated thorium hydroxide by boiling the chloride soln. for some minutes with potassium azide. G. Wyrouboff and A. Verneuil say that some cerium hydroxide is precipitated with the thorium hydroxide. W. B. Giles precipitated thorium by adding lead carbonate to a soln. of the nitrate in which the cerium had been reduced to the cerous state by hydrogen sulphide. The precipitate was dissolved in nitric acid, the lead precipitated by hydrogen sulphide, and the thorium by ammonia. W. Muthmann and E. Baur found that the thorium accumulates in the first precipitate obtained when a 6 per cent. soln. of potassium chromate is added to a soln. containing thorium nitrate. L. de Boisbaudran precipitated the thorium by cuprous oxide. A. Rosenheim, M. Koss, and F. Wirth precipitated thorium quantitatively by sodium hypo-phosphate; from soln. with 15 per cent. of free sulphuric acid the rare earths remain in soln. The thorium hypophosphate is then boiled with alkali hydroxide, converted into oxalate, etc. R. J. Carney and E. D. Campbell said that sodium pyrophosphate acts similarly. All these processes are detailed in connection with general processes for the separation of the rare earths.

M. Delafontaine separated zirconia from thoria by the following process:

> The powdered mixture (ore or oxides) is fused in a platinum crucible with twice its weight of acid potassium fluoride, KHF_2. The zirconia is separated as potassium fluo-zirconate, K_2ZrF_6, from the solidified mass by means of boiling water containing a few drops of hydrofluoric acid. The insoluble fluorides are decomposed by sulphuric acid, and ignited below a dull red heat, which will leave thorium, cerium, and other earths as sulphates. Silica, if present, escapes as silicon fluoride. The sulphates are dissolved in water and precipitated by oxalic acid, the oxalates being treated by a sat. hot soln. of ammonium oxalate; the thorium salt is dissolved and cerium left. The ignited oxalates leave the oxides in good condition for further work. Zirconia is thrown down from its fluo-salt by ammonium hydrate. Titanium, if present in the original mixture, is found as fluo-titanate soluble in hot water.

To separate the rare earths, R. Chavastelon treated a soln. of the chlorides with ammonia and hydrogen dioxide, and digested the precipitate with a soln. of an alkali hydrocarbonate. The cerium and thorium oxides pass into soln., and may be separated by either of the following processes: (1) reduction of the peroxides, and formation of the sulphites by the action of sulphurous acid, and the precipitation of thorium by hydrogen dioxide from a hydrochloric acid soln. of these salts; (2) reduction of the brown soln. of ceric and thoric carbonates with sulphurous acid in the presence of sufficient sodium carbonate to keep the whole of the thorium dissolved as the double sodium sulphite. In the latter process, the soln. must be constantly agitated during the addition of the sulphurous acid in order to prevent the formation of acid sulphite, otherwise some of the cerium will be dissolved whilst traces of thorium will be precipitated. R. Chavastelon also recommended adding a neutral soln. of the salts of thorium and the rare earths to a sat. soln. of

sodium sulphite; the thorium remains in soln. while the other elements are precipitated as sulphites. The precipitate is practically free from the rare earths, but the little which has escaped precipitation is recovered by converting the sulphites to chlorides, and treating the soln. by the hydrogen dioxide process. H. Grossmann said that this method is not of any technical value, but A. Batek said it can be used for separating the ceria earths from thoria. The Lindsay Light Co. used a modification of the fluoride process—*vide* rare earths.

J. J. Chydenius added sodium thiosulphate to a neutral or feebly acid soln. of the thorium salt, and on boiling the mixture or allowing it to stand, thorium thiosulphate and sulphur are precipitated, while cerium and zirconium are not precipitated. The precipitation, however, is not complete. R. Hermann, R. Bunsen, and O. N. Witt used modifications of the thiosulphate process. A. Rosenheim and co-workers devised a process based upon the fact that from a strongly acid soln. thorium is completely precipitated by the addition of hydrofluosilicic acid or a soluble silicofluoride, whereas the elements of the cerite and ytterbia earths remain almost entirely in soln. R. J. Meyer and M. Speter purified thoria from monazite by the iodate process :

Fifty grams of the sample are heated with 100 c.c. of conc. sulphuric acid for six hours at 250°, and, when cold, 500 c.c. of cold water are added. The soln. is filtered and, when cold, diluted to 1 litre, and 100 c.c. are then taken for analysis. After adding 50 c.c. of nitric acid, of sp. gr. 1·4, and cooling, a cold soln. of 15 grms. of potassium iodate in 50 c.c. of nitric acid and 30 c.c. of water is added, and, after half an hour, the thorium iodate is collected and washed with a soln. containing 2 grms. of potassium iodate in 50 c.c. of dil. nitric acid and 200 c.c. of water. The precipitate is returned to the beaker, and again stirred and washed. It is now again transferred to the beaker by means of a jet of hot water, heated to boiling, and dissolved in 30 c.c. of strong nitric acid ; addition of 4 grms. of potassium iodate dissolved in hot water causes it to reprecipitate. The precipitate is now collected on the same filter and washed as before, and is then quite free from cerium. It is dissolved in hydrochloric acid with the aid of sulphur dioxide, and precipitated with ammonia at the boiling heat. The hydroxide is washed with boiling water, redissolved in dil. hydrochloric acid, and precipitated with excess of oxalic acid. The precipitate is washed with water, acidified with hydrochloric acid, and then ignited to oxide.

L. Fernandes recommended separating thoria from the rare earths by the following process :

The mixture of hydroxides precipitated by means of ammonia is washed repeatedly with boiling water, and then dissolved in dil. sulphuric acid. The soln. is filtered and treated with excess of thallous sulphate ; the cerium metals are precipitated, and the precipitate is removed by filtration. The filtrate is heated on a water-bath until more than one-third of the solvent is expelled, and then filtered, to free it from the last traces of tervalent earth metals. When cooled, the clear liquid deposits the first fraction, which contains pure thorium. The soln. is again evaporated until almost conc. sulphuric acid is obtained, the various thorium fractions which separate being removed. When the remaining strongly acid soln. is heated to boiling, the final traces of thorium separate as the normal sulphate, which is removed by filtration through asbestos or a porous crucible. The zirconium compounds separate when the filtrate is cooled.

Another set of processes, involving the use of organic compounds, has been also discussed in connection with the rare earths. Thus, I. Kreidl and G. Heller used the ethylsulphate process. C. R. Böhm converted the hydroxide into acetate, and found that thorium acetate is virtually insoluble in water. F. Garelli and G. A. Barbieri used the salicylic acid process ; A. C. Neish, and A. Kolb and H. Ahrle, the *m*-nitrobenzoic acid process ; F. G. Metzger, the fumaric acid process ; T. O. Smith and C. James, the sebacic acid process ; G. Urbain, and C. James, the acetylacetonate process ; and A. Kolb, the aniline process. J. W. Marden, and co-workers found thorium can be electrodeposited from a soln. obtained by dissolving the hydroxide in hydrofluoboric acid together with lead hydroxide or carbonate.

The separation of the radioactive constituents of thorium has been discussed by E. Rutherford and F. Soddy,[2] H. Schlundt and R. B. Moore, G. C. Ashman,

H. N. McCoy and W. H. Ross, B. Keetmann, etc.   The adsorption of thorium salt from a soln. containing uranium-X, has been discussed by A. Ritzel,[3] F. Soddy, and H. Freundlich and co-workers—*vide infra*.

§ 3. The Radioactivity of Thorium

Soon after the discovery of radioactivity of uranium, G. C. Schmidt,[1] and independently M. S. Curie, found that thorium and its compounds, and thorium minerals are also radioactive.   The rays emitted can discharge a charged electroscope, and fog photographic plates.   Thorium products emit Becquerel's rays, that is, a mixture of α-, β-, and γ-rays ; the latter are more intense and penetrating than those of uranium.   Thorium products also emit a radioactive gas which retains

its activity for about ten minutes. The radioactivity of thorium products is a complex effect due to the presence of a series of transformation products derived from thorium itself : Thorium→Mesothorium-1→mesothorium-2→Radiothorium →thorium-X→thorium emanation→active deposit of thorium. The radioactivity of freshly prepared thorium compounds is not constant, but decreases slowly for some years, reaches a minimum, and then slowly increases, and finally attains a maximum value. The variation is due to the growth in thorium of new radio-active substances which ultimately attain an equilibrium and constant value.

The ratio of uranium to thorium in the thorium minerals is far from constant, and this is taken to mean that it is improbable that there is any genetic relation between the two. This is illustrated by Table II, collected from results by

TABLE II.—RATIO OF URANIUM TO THORIUM IN SOME THORIUM MINERALS.

Mineral.	Per cent.		Mineral.	Per cent.	
	U	Th		U	Th
Auerlite	—	61–63	Sipilite	2·86	4·92
Freyalite	—	24	Gadolinite .	2·94	8·60
Crytolite	—	13	Uranothorite	1·0–10·0	35–45
Orthite ; allanite	—	8·8	Crystolite .	3·67	5·05
Monazite sand	—	1·0–2·5	Samarskite	3·0–15·0	4
Ancylite	—	0·17	Thorianite .	9·0–13·0	65–77
Xenotime .	0·5–3·0	0·5–3·0	Thorite	c. 9	c. 45
Orangite	1	65	Thorogummite .	18	36
Fergusonite ; tyrite	1·5–6·0	1·0–3·0	Mackintoshite	20	42
Æschynite .	2–9	1–8	Cleveïte	60	6
Euxenite	2·84	2·72	Bröggerite .	c. 66	c. 14

R. J. Strutt, etc. S. Meyer has also studied the thorium uranium content of minerals. W. R. Dunstan found that Cingalese thorite contains very little uranium ; according to F. Soddy's analysis, the mineral contains 1·80 per cent. of residue insoluble in hydrochloric and hydrofluoric acids, and

ThO_2	SiO_2	Fe_2O_3	Ce_2O_3	ZrO_2	P_2O_5	Al_2O_3	U_3O_8	CaO	PbO	H_2O
61·95	11·91	5·18	4·99	3·92	0·66	0·80	0·85	0·40	0·39	7·06

In the early days of the discovery of the radioactivity of thorium, the question was raised whether thorium is primarily a radioactive element under all conditions independently of the source from which it is obtained. K. A. Hofmann and co-workers, and C. Baskerville maintained that thorium is inactive *per se*, and shows radioactivity only under certain conditions. Thus, K. A. Hofmann and E. Strauss maintained that the radioactivity of many thorium minerals is due to the contained uranium. K. A. Hofmann and F. Zerban claimed to have made inactive thorium from uranium-free monazite ; C. Baskerville and F. Zerban also claimed to have obtained inactive thorium from uranium-free minerals. These conclusions, said M. S. Curie, *demandent confirmation et ne sont pas en accord avec d'autres recherches sur l'activité du thorium dans ses minerais*, e.g. those of H. M. Dadourian, H. N. McCoy and W. H. Ross, A. S. Eve, and B. B. Boltwood. Further, F. Zerban, C. Winkler, and G. F. Barker also showed that all commercial preparations of thorium contain some uranium. K. A. Hofmann and F. Zerban showed that all the preparations of thorium became less active when kept for 1½ to 3 years. C. Basker-ville, and W. Crookes obtained indications of another constituent in thorium, but the result is now explained by the complex nature of the radioactive decay products contained in thorium. As M. S. Curie said : *Radioactivity is a specific property of thorium.*

There is no method known for separating radiothorium from thorium, and it is

very difficult to prepare thorium free from all its decay products. In order to eliminate mesothorium, the soln. is treated with a barium salt, and barium sulphate precipitated. This carries down the mesothorium. The radiothorium still present in the soln. is allowed to decay; at the same time, mesothorium gradually grows in the soln., and it furnishes more decay products. Hence, the mesothorium must be repeatedly removed to prevent the growth of more radiothorium. In about $6\frac{1}{2}$ years, the radiothorium can be reduced to one per cent., and in 20 years, to 0·1 per cent. The study of radioactively pure thorium is complicated by the disturbing effects due to the presence of the transformation products. M. de Broglie and J. Cabrera studied the γ-rays of the thorium family.

The at. wt. of thorium is taken to be 232. Thorium itself emits feeble α-rays which have a range of 2·72 cm. in air at 15°, and an initial velocity of $1·40 \times 10^9$ cm. per sec. H. Geiger and E. Rutherford found the number of α-particles emitted by a gram of thorium in equilibrium with its decay products to be $2·7 \times 10^4$ per sec.; and they estimate that without its decay products $4·5 \times 10^3$ particles per sec. or $1·42 \times 10^{11}$ per year would be emitted by thorium alone. Since a mol of gas contains $6·07 \times 10^{23}$ molecules, a gram of thorium contains $2·61 \times 10^{21}$ atoms; and the decomposition constant in reciprocal years is $5·44 \times 10^{11}$; this corresponds with a half-life period of $1·28 \times 10^{10}$ years; an average life period of $1·84 \times 10^{10}$ years; and a radioactive constant $\lambda = 1·7 \times 10^{-18}$ sec. In view of the long life period of mesothorium it is probable that the thorium was not in equilibrium with its decay products. This would make the number of α-particles emitted too small. and the half-life period too long. H. N. McCoy estimated the half-life period of thorium to be $1·86 \times 10^{10}$ years, the average life period, $2·5 \times 10^{10}$ years; and the radioactive constant $\lambda = 1·2 \times 10^{-18}$ sec. G. C. Ashman found for the half-life period $1·86 \times 10^{10}$ years; L. Meitner, $2·37 \times 10^{10}$ years; B. Heimann, $1·5 \times 10^{10}$ years; H. Geiger and J. M. Nuttall, 10^8 years. A. Fleck discussed the isotopy of thorium, radioactinium, and uranium-X.

After the discovery of radiothorium, it was assumed that this radioactive element is formed directly from thorium itself. In 1906, as a result of the work of B. B. Boltwood, H. M. Dadourian, H. N. McCoy and W. H. Ross, and A. S. Eve, it was shown that the radioactivity of thorium minerals is directly proportional to the contained thorium, when due allowance is made for the contained uranium. The radioactivity of commercial thorium salts, however, was much smaller, in some cases not more than half of that normally shown by the minerals. It was naturally supposed by B. B. Boltwood that the deficiency was due to the separation of part of the radiothorium during the chemical purification of the thorium, and hence it was inferred that the half-life period of radiothorium must be six years but O. Hahn [2] found the half-life period to be about two years. O. Hahn, therefore, suggested that an unknown rayless product was formed between thorium and radiothorium. On testing this hypothesis, he found that the radioactivity of freshly prepared thorium salts was normal, but the activity gradually decreased with age attaining a minimum in about 4·6 years; the radioactivity then rose towards the initial normal value. Taking the half-life period of radiothorium as two years, he inferred that the intermediate rayless product had a half-life period of about $5\frac{1}{2}$ years. This was confirmed by H. N. McCoy and W. H. Ross. The intermediary product was named **mesothorium,** and later **mesothorium-1,** MsTh₁ —from $\mu\acute{\epsilon}\sigma\sigma s$, in the middle. E. Rutherford found the time curves of the decay of the activity of thorium preparations agreed well with these assumptions. H. N. McCoy and L. M. Henderson found the ratio of mesothorium to thorium in thorianite to be $0·535 \times 10^{-7}$ to $0·535 \times 10^{-7}$; in Indian monazite, $0·507 \times 10^{-7}$; in Brazilian monazite, $0·484 \times 10^{-7}$; and in thorium nitrate, $0·508 \times 10^{-7}$ to $0·559 \times 10^{-7}$. The average $0·52 \times 10^{-7}$ is about one-sixth the value of the Ra : U-ratio, $3·32 \times 10^{-7}$.

In preparing mesothorium-1, it is an advantage to use salts as old as possible so that the proportion of mesothorium-1 may approach the equilibrium value. According to B. B. Boltwood, mesothorium-1 can be separated from thorium by

adding ammonia to a dil. soln. of the nitrate for 80–90 per cent. of the meso-thorium-1 then remains in the filtrate. He also noted that mesothorium-1 is entrained when barium is precipitated as sulphate or carbonate from a soln. of a thorium salt. F. Soddy showed that the mesothorium-1 is not absorbed by the barium sulphate, but that the co-precipitation depends on a chemical relationship between mesothorium-1 sulphate and barium sulphate. If radium be present, it too will be also precipitated. F. Soddy, and W. Marckwald could not separate radium from mesothorium-1 by the fractional crystallization of a mixture of the two ; and mesothorium-1 and radium are considered to be isotopic. R. K. Strong, and J. L. Nierman studied the fractional crystallization of barium bromide mixed with radium and mesothorium bromides. Mesothorium-1 can be obtained from soln. of an aged preparation of thorium nitrate by adding ferric chloride, and treating the soln. at 70°–80° with sodium carbonate. The precipitated basic ferric carbonate entrains the mesothorium-1. According to S. Meyer and E. von Schweidler, radium-free mesothorium-1 is obtained by separating mesothorium and radium from a thorium preparation by the barium sulphate process ; and after some years, precipitating the mesothorium-1 which has grown in the pre-paration. If the thorium was free from uranium, and ionium, no further radium would have been simultaneously formed.

Mesothorium preparations are used in medicine as a substitute for radium prepara-tions. Commercial mesothorium contains mesothorium-1, mesothorium-2, radiothorium, thorium-X, etc. Thorium minerals, monazite sand, or old gas mantles are used as raw material. This is digested with sulphuric acid. Part of the mesothorium is dissolved by the acid, but most remains undissolved. To prevent the dissolution of the meso-thorium, a little barium carbonate or chloride is added. The liquid must be stirred so that the barium sulphate is formed throughout the whole mass of liquid ; and enough barium salt should be added to precipitate all the mesothorium and radium in the soln. The mixture is then treated with sodium carbonate to convert the sulphates to carbonates, or the sulphates are transformed into sulphides. The products are dissolved in hydro-chloric acid, and the chlorides purified as in the case of radium salts. F. Soddy, and C. Schwab have patented modifications of the process. F. Glaser precipitated mesothorium and thorium-X from a soln. of a thorium salt containing a little lead acetate, by the addition of dil. sulphuric acid. Other lead salts do not behave like lead sulphate. H. Schlundt has discussed the general methods of preparation from monazite.

The chemical properties of mesothorium resemble those of radium with which it is isotopic. M. S. Curie estimates the radium and mesothorium in mixtures by the measurement of the heat effect due to the emission of α-rays. The at. wt. of mesothorium-1 is 228. Mesothorium-1 is either rayless, or else it emits very soft β-rays. It decays into mesothorium-2. According to O. Hahn, and H. N. McCoy and W. H. Ross, the half-life period is 5·5 years ; the average-life period, 7·9 years ; and the radioactive constant, $\lambda = 4·0 \times 10^{-9}$ sec., or 0·126 year. L. Meitner gave 6·7 years for the half-life period of mesothorium-1. If q_0 mgrm. of mesothorium are produced per annum by thorium, and N denotes the number of mgrm. of meso-thorium present at the time t, then λN-mgrm. of mesothorium change every year when λ is the radioactive constant of mesothorium. The rate of increase of meso-thorium, dN/dt, is equal to the rate of production q, less the rate of change, or $dNdt = q - N\lambda$. When t is very great the number of particles of mesothorium reaches a maximum, or $N = N_0$ when t is infinite ; and $N = 0$ when $t = 0$. Then, by integration, the number of milligrams of mesothorium present at the time t is $N = N_0(1 - e^{\lambda t})$. For equilibrium, the amount, q_0 mgrm., of mesothorium produced per annum is equal to the number of milligrams, λN_0, which change per annum, or $q_0 = \lambda N_0$. Hence,

$$N = \frac{q_0}{\lambda}(1 - e^{\lambda t}) \quad \ldots \ldots \ldots \quad (1)$$

100,000 kgrm., or 10^{11} mgrm. of thorium are used approximately per annum in making gas mantles. Then, if the average-life period of thorium is $2·6 \times 10^{10}$ years, and of mesothorium 7·9 years, and remembering that the radioactive constant is

the reciprocal of the average-life period, $q_0 = 7\cdot9 \times 10^{11} \div 2\cdot6 \times 10^{10}$, or $q = 30$ mgrm., it follows from (1) that nearly 300 mgrm. of mesothorium will be produced per annum by 100,000 kgrm. of thorium.

Commercial mesothorium is a mixture of mesothorium, radiothorium, and other decay products. The β- and γ-ray activity rises to a maximum in about $2\cdot3$ years and the half-life period is $5\cdot5$ years. It is used as a convenient source of radioactive rays. Since the raw materials usually contain uranium and radium, commercial mesothorium also contains radium. About a quarter of the γ-ray activity of commercial mesothorium is due to radium. The activity of commercial samples is often expressed in terms of the γ-ray activity of radium in equilibrium with its decay products. Thus, " 5 mgrm. of mesothorium " indicates that one month after its separation the γ-ray activity of the meso-thorium plus that of the associated radium is eq. to 5 mgrm. of radium bromide. The activity of preparations of mesothorium is usually greater than that of an equal weight of radium bromide. After having been kept a year, much radiothorium is present. A soln. of an old preparation mixed with a little thorium nitrate and treated with ammonia gives a precipitate of radiothorium, while mesothorium and thorium-X remain in soln.

O. Hahn noticed that a few hours after rayless mesothorium-1 has been prepared, it emits β- and γ-rays. This was traced to the change of mesothorium-1 into another radioactive product of short life, which he called **mesothorium-2**, MsTh$_2$. He found that the two products can be separated by adding a trace of zirconium or thorium salt to the active soln., and precipitating with ammonia ; mesothorium-2 collects in the precipitate, while mesothorium-1 remains in the filtrate. H. N. McCoy used an aluminium salt, and W. Marckwald a ferric salt in place of O. Hahn's zirconium or thorium salt. In order to separate mesothorium-2 from thorium-B or thorium-C, a little lead, bismuth, or mercury salt is added, and the soln. treated with hydrogen sulphide, the mesothorium-2 remains in the filtrate. In order to remove radiothorium from mesothorium-2, a trace of a thorium or related salt is added, and precipitated with hydrogen dioxide. To prepare active films of mesothorium-2, H. N. McCoy and C. H. Viol recommend co-precipitation with barium sulphate from faintly acid soln. L. Meitner found that mesothorium-2 containing small proportions of the thorium active deposit is separated from a mesothorium soln. by precipitating iron in the soln. by ammonia. After the first few precipitations at daily intervals, the radiothorium and thorium-X are removed, and then the precipitates, obtained by a trace only of iron, consist of mesothorium-2 and a little thorium-B. By electrolysis of the hydrochloric acid soln. using a platinum cathode, the iron and the thorium-B are deposited. The soln. is nearly neutralized, boiled vigorously and electrolyzed with a silver cathode, when the mesothorium-2 is deposited. W. P. Widdowson and A. S. Russell separated mesothorium-2 from its parent substance by the addition of thorium, and precipitation with ammonia.

According to D. K. Yovanovitch, a conc. soln. of the chlorides of barium and radioactive elements was treated with hydrochloric acid in the cold. The precipitated barium chloride carried down with it mesothorium-I, thorium-X, and radium, leaving mesothorium-I radiothorium, and the active residue in soln. By this process, repeated at intervals, meso-thorium-I was obtained in the acid soln., nearly pure and practically free from barium. The final purification of mesothorium-I was carried out by repeated co-precipitation with salts of iron or aluminium, and further by reprecipitation as hydroxide. To eliminate radiothorium a trace of thorium was added and later removed by means of hydrogen dioxide. Thorium-C and thorium-B were removed by precipitation with lead and bismuth, which in turn were removed as sulphides. Mesothorium-I in soln. with elements of the cerium group was fractionally precipitated as oxalate, hydroxide, and as the double sulphate. Mesothorium-I in the presence of lanthanum and praseodymium appeared in greater quantity in the early fractions, but when mixed with neodymium and samarium was more conc. in the last fractions. In the fractionation of the double nitrates of the rare earths and ammonium, mesothorium-I tends to accumulate with lanthanum rather than with samarium.

The at. wt. of mesothorium-2 is 228. While the general properties of meso-thorium-1 resemble those of the alkaline-earth family, those of mesothorium-2 belong to the rare-earth group. Mesothorium-2 is isotopic with actinium, and the nearest member of its family in the periodic table is lanthanum. A. Fleck dis-cussed the isotopy of mesothorium-2 and actinium. Mesothorium-2 emits β- and

γ-rays, but not α-rays. The β-rays are not homogeneous, but show, according to O. von Baeyer and co-workers, a magnetic spectrum involving rays of velocity 1·11, 1·17, 1·29, 1·50, 1·71, 1·80, and $1·98 \times 10^{10}$ cm. per sec. There is also a band with a velocity 2·1 and $2·85 \times 10^{10}$ cm. per sec. thought to belong to thorium-D. D. H. Black measured the β-ray spectrum of mesothorium-2 ; and J. Thibaud, and D. K. Yovanovitch the magnetic spectrum of the γ-rays from mesothorium-2. The absorption coeff. of the β-rays of velocity $1·17 \times 10^{10}$ cm. per sec. is 20·3 cm.$^{-1}$ of aluminium, and those of velocity $1·80 \times 10^{10}$ cm. per sec. 38·4 cm.$^{-1}$ of aluminium. F. Soddy and co-workers found the γ-rays from mesothorium-2 to be rather less penetrating than those from radium. They found the absorption coeff. of the γ-rays in cm. to be:

Pb	Sn	Zn	Cu	Fe	S	Al
0·620	0·305	0·300	0·373	0·316	0·083	0·116 and 26

E. Rutherford and H. Richardson also made observations on this subject. Mesothorium-1 is the parent of mesothorium-2, the latter decays into radiothorium. O. Hahn found the half-life period to be 6·20 hrs. ; H. N. McCoy and C. H. Viol, 6·13 hrs. ; and W. P. Widdowson and A. S. Russell, 5·95 hrs. O. Hahn's value for the average-life period is 8·9 hrs., and for the radioactive constant, $\lambda = 3·1 \times 10^{-5}$ per sec. or 0·112 per hr. W. P. Widdowson and A. S. Russell gave 0·116 per hour for the disintegration constant of mesothorium-2. P. Lemay and L. Jaloustre found mesothorium acted as a catalyst in oxidation processes in virtue of the α-radiations and not the formation of ozone.

O. Hahn [3] ôbtained a very active substance in the residues remaining after the separation of thorium from thorianite ; he called it **radiothorium,** RaTh. G. A. Blanc found what proved to be radiothorium in the sediment deposited by the hot springs of Echaillon and of Salins Moutiers. The radiothorium is here assumed to have been derived from the mesothorium dissolved by the water, and carried to the surface. J. Elster and H. Geitel likewise observed what proved to be radiothorium in the sediment from the waters of Baden-Baden ; and H. Mache, in the waters of the Gasteiner Reissacherit.

According to O. Hahn, H. N. McCoy and co-workers, radiothorium is chemically identical with thorium, and it is accordingly precipitated from a soln. of mesothorium by ammonia, the mesothorium remains in soln., and thorium-X, if present, likewise remains in the filtrate. Thorium-B, and thorium-C, if present, are precipitated with hydrogen sulphide, preferably by the addition of a little lead, mercury, or bismuth to the soln. before treatment. The radiothorium can then be precipitated with ammonia. Radiothorium is best co-precipitated with a little aluminium or ferric hydroxide ; it can also be precipitated with basic ferric carbonate by adding sodium carbonate to the soln. About 50 per cent. is entrained with barium sulphate when the latter is precipitated from acid soln. of radiothorium. About 5 per cent. of the radiothorium is entrained with these sulphates. If the radiothorium be admixed with the isotopic uranium-X_1 and radioactinium, the soln. is allowed to stand for some months when these products will have decayed. Freshly prepared radiothorium may contain mesothorium-2 which will have decayed in 2–3 days ; but thorium-X will have been formed. O. Knöfler found that radiothorium can be electrodeposited by the electrolysis of soln. containing a relatively large proportion of radiothorium and very little thorium.

The at. wt. of radiothorium is 228. According to G. von Hevesy, the diffusion constant of radiothorium is 0·33 sq. cm. per day, and this value is characteristic of a quadrivalent element. Radiothorium is isotopic with thorium, ionium, uranium-X_1, and radioactinium. Hence, if the starting material for the preparation of radiothorium be not free from uranium, the three last-named isotopes may be all present ; and if the mesothorium contains thorium, then it too will be present. While the direct parent of radiothorium is mesothorium-2, the direct decay product is thorium-X. Radiothorium free from its decay products emits α-rays of range

3·87 cm. in air at 15°, and initial velocity $1·58 \times 10^9$ cm. per sec. at 0°. O. von Baeyer and co-workers found that radiothorium emits β-rays with velocities $1·41 \times 10^{10}$ and $1·53 \times 10^{10}$ cm. per sec.—the latter were formerly ascribed to thorium-X. J. Chadwick and A. S. Russell also observed the emission of very soft γ-rays by radiothorium. L. Meitner found that the β-ray change of thorium-X is free from γ-rays. O. Hahn gave 2 years for the half-life period, G. A. Blanc, 737 days=2·02 years, and M. S. Leslie, 710 days. Assuming the half-life period is 2 years, the average life period is 2·9 years, and the radioactive constant, $\lambda=1·09 \times 10^8$ sec. or 0·347 year. P. Lemay and L. Jaloustre found radiothorium acted as a catalyst in oxidation processes.

The time-variation in the activity of mesothorium, and of radiothorium, is obtained from the respective relations:

$$\text{Mesothorium, } M = M_0 e^{-\lambda_1 t} \text{ ; Radiothorium, } R = R_0 e^{-\lambda_2 t} \quad . \quad . \quad (2)$$

FIG. 2.—Decay Curves of Meso-thorium and Radiothorium.

where M and R, respectively, denote the amounts of mesothorium and radio-thorium at the time t; M_0 and R_0, the respective amounts initially present; and $\lambda=0·1265$ year and $\lambda_2=0·3466$ year, the corresponding radio-active constants. The corresponding curves for each element when $M_0=1$, and $R_0=1$ are shown in Fig. 2. Since mesothorium-1 and meso-thorium-2 are in equilibrium two days after the preparation, the two may be assumed as one product with a half-life period of·5·5 years, and emitting β- and γ-rays; the mesothorium is transformed into radiothorium and its decay products. If dQ be the amount of radiothorium formed in unit time, this is supplied by the amount, $\lambda_1 M$, of mesothorium less the amount, $\lambda_2 Q$, of radiothorium changed into thorium-X, or $dQ/dt=\lambda_1 M-\lambda_2 Q$; but, on substituting for M, from (2), and integrating for $Q=0$ when $t=0$, it follows that the amount, Q, of radiothorium present at the time t is:

$$Q = \frac{\lambda_1 M_0}{\lambda_2 - \lambda_1} (e^{-\lambda_1 t} - e^{-\lambda_2 t}) \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

The curve for $M_0=1$ is shown in Fig. 2. Since radiothorium alone emits α-rays, and the successive short-lived products together emit four α-ray products, the number of α-ray particles emitted at the time t is $5\lambda_2 Q$, so that the α-ray activity is proportional to the curve for the production of radiothorium. E. Rutherford showed that the β- or γ-ray activity is proportional to $\lambda_1 M + k\lambda_2 Q$, where k is a constant dependent on the relative ionization due to the β- or γ-rays from mesothorium and the decay products thorium-C and thorium-D. The γ-ray activity when $k=1$ passes through a maximum in about 2·3 years, and then decays exponentially with the period of mesothorium. W. Bothe differentiated radium, mesothorium, and radiothorium by γ-ray measurement.

W. Crookes, and C. Baskerville obtained evidence of the presence of a radio-active substance in thorium compounds. E. Rutherford and F. Soddy showed that if ammonia be added to a soln. of a thorium salt, the thorium is precipitated as hydroxide, but a radioactive substance remains in the filtrate which is chemically free from thorium. The filtrate was evaporated, and the ammonium salts driven off by ignition. The residue was found to be, weight for weight, several thousand times more active than the thorium from which it was obtained. They named the active constituent **thorium-X,** ThX, by analogy with W. Crookes' uranium-X. The active constituent so obtained was largely contaminated with impurities from the thorium. It was also found that an active constituent could be separated from thorium oxide by shaking it with water for some time, and then filtering and evaporating the soln. W. Crookes found that by fractionally crystallizing thorium

nitrate six times, the product at one end of the series was about three times as radioactive as that at the other end. Thorium sulphate gave negative results. H. Schlundt and R. B. Moore found that if pyridine, fumaric acid, or metanitrobenzoic acid be employed as precipitant in place of ammonia, the thorium-X is also accompanied by thorium-B. H. N. McCoy and C. H. Viol obtained thorium-X from aged radiothorium. A little aluminium salt is mixed with the soln., and ammonia added. The filtrate containing thorium-X and radiothorium is mixed with a trace of thorium salt and precipitated with ammonia. The acidified filtrate is mixed with a little lead, mercury, or bismuth salt, and treated with hydrogen sulphide. Thorium (-B, -C, and -D) sulphide collects with the precipitated sulphide. The filtrate is mixed with a little barium salt, and sulphuric acid. The thorium-X is precipitated with the barium sulphate. A mixed soln. of barium and thorium-X chlorides or nitrates was shown by D. Strömholm and T. Svedberg to furnish on crystallization an isomorphous mixture of the thorium-X and barium salts. According to F. von Lerch, the induced thorioactive matter, but not thorium-X, is precipitated from the hydrochloric acid soln. of thorium-X by magnesium, iron, zinc, amalgamated zinc, nickel, lead, copper, or aluminium. The induced thorioactive matter, sometimes along with traces of thorium-X, is also precipitated on electrolysis of acid thorium-X soln.; but thorium-X is precipitated along with metals from alkaline soln. According to J. Lorenzen, when a colloidal soln. of thorium oxide is dialyzed, thorium-X passes through the membrane, yielding a pure soln. The thorium-X is regenerated continuously from the radiothorium present in ordinary thorium oxide, and further quantities can therefore be separated by renewing the distilled water in the dialyzer. The colloidal thorium oxide may be prepared by treating a conc. soln. of thorium nitrate with ammonia, washing the precipitated thorium hydroxide, and digesting it with a small quantity of water after addition of a trace of thorium nitrate. The Deutsche Gasglühlicht Aktien-Gesellschaft have patented a process for the preparation of thorium-X in commercial quantities. According to F. Glaser, the precipitation of thorium-X from a thorium soln. obtained from monazite sand is conditioned by the presence of lead which, as lead sulphate, absorbs thorium-X, and thorium-X may be separated from any thorium soln. containing sulphuric acid by the addition of a little lead acetate. Other lead salts do not behave like lead sulphate in this respect, so that by treating the radioactive lead sulphate with sodium carbonate soln., dissolving the washed residue in hydrochloric acid, and precipitating with hydrogen sulphide, the lead may be separated as sulphide, leaving thorium-X in soln.

The at. wt. of thorium-X is 224. According to G. von Hevesy, the diffusion constant is 0·66 sq. cm. per day in agreement with that of a bivalent element. Thorium-X is isotopic with radium, mesothorium-1, and actinium-X. It follows all the reactions characteristic of radium, mesothorium-1, etc., and it belongs to the alkaline earth family. As indicated above, D. Strömholm and T. Svedberg found it crystallizes isomorphously with barium salts. Thorium-X emits α-rays. O. Hahn gave 5·7 cm. for the range of the α-particles, while H. N. McCoy and C. H. Viol gave 4·08 cm. at 15° in air, and H. Geiger and J. M. Nuttall gave 4·3 cm. at 150; the initial velocity of the α-rays is $1·64 \times 10^9$ cm. per sec. The β-rays attributed by O. von Baeyer and co-workers to thorium-X may belong to radiothorium. E. Rutherford and F. Soddy's first estimate for the half-life period was about 4 days. F. von Lerch, and H. N. McCoy and C. H. Viol, gave 3·64 days; M. Levin, 3·65; and J. Elster and H. Geitel, 56 days. Assuming the best representative value is 3·64 days, the average-life period is 5·25 days; and the radioactive constant, $\lambda = 2·20 \times 10^6$ sec. or 0·190 day. G. H. Briggs studied the electric change carried by thorium-X atoms. The parent of thorium-X is radiothorium, the first decay product is thorium emanation. E. Rutherford and F. Soddy found that when the thorium-X salt is separated from a thorium salt, the former completely loses its activity in a month's time, while the latter had completely gained its activity. The decay curve of the activity, I, of thorium-X was represented by

$I=I_0e^{-\lambda t}$, where I represents the activity of the preparation at the time t, and I_0 the initial activity, λ is a constant; conversely the recovery of activity by the thorium is represented by $I=I_0(1-e^{-\lambda t})$, where the constant λ is the same as before. P. Lemay and L. Jaloustre found thorium-X acted as a catalyst in oxidation processes.

Some thorium salts—particularly the oxide—behave very irregularly in the ionization of the ambient air. R. B. Owens[4] showed that the irregularities are produced by currents of air, and in 1900, E. Rutherford showed that thorium compounds continuously produce a radioactive emanation—**thorium emanation,** or **thoron,** ThEm—which has the properties of a gas, and which is the source of the disturbances observed by R. B. Owens. These observations were confirmed by E. Dorn, and the general properties of the emanation were studied by E. Rutherford and F. Soddy. Thorium emanation was discovered before the radioactive emanation from radium and actinium. A. Lepape discussed the detection of thorium emanation in thermal springs by the method of induced radioactivity.

Thorium emanation has a comparatively short life-period—approximately an hour. E. Rutherford found that a gram of thorium is in equilibrium with 1.2×10^{-13} mgrm. of the emanation; and, assuming the decay of the emanation is about 0·01 grm. per sec., the corresponding volume is 1.2×10^{-14} c.c. The gas is occluded by thorium and its compounds. It is obtained by the same methods as those employed for radium and actinium emanations. E. Rutherford and F. Soddy found that the occluded emanation is more readily driven off from some preparations than from others. In general it is more readily obtained from moist than from dry compounds. It is not so easily obtained from dried thorium oxide as it is from the hydroxide; it is retained more tenaciously by thorium sulphate and nitrate than it is by the carbonate.

Observations by H. A. Bumstead, J. E. Burbank, A. Gockel, G. A. Blanc, and C. Runge have shown that part of the radioactivity of atm. air is due to the contained thorium emanation. H. M. Dadourian found that the ratio of radium emanation to thorium emanation is 30000 to 50000 : 1 at Newhaven (America), and 20000 to 30000 : 1 at Rome. W. E. Wilson obtained 9000 to 18000 : 1 for the former and 2600 to 4000 : 1 for the latter; and at Manchester he found 3700 : 1. D. Pacini found on the Apennines, 2300 to 15000 : 1, according to the strength of the wind; and he found that the amount of the emanation in air decreased with increasing barometric press. H. M. Dadourian found thorium emanation in underground air, and in the air of soils. J. C. Sanderson found an amount of thorium emanation in the soils corresponding with 1.35×10^{-6} grm. of thorium, this represents 1.67×10^{-19} c.c. of thorium emanation; the corresponding value for radium emanation is 1.44×10^{-16} c.c., and the ratio of the latter to the former is nearly 8500 : 1. G. A. Blanc, G. von der Borne, C. Schäfer and C. Seebohm, O. Angelucci, P. Artmann, G. Feliciani, and K. Aschoff have reported thorium emanation in gases, waters, and sediments from different mineral springs.

The mol. wt. of thorium emanation cannot be obtained from the density of the gas because so little of the gas can be made at one time. Attempts have been made to deduce values from the diffusion coeff. M. S. Leslie found the diffusion coeff. in air at 18° to be less than 0·85 sq. cm. per sec. E. Rutherford obtained the coeff. 0·097. W. Makower compared the diffusion coeff. of radium and thorium emanations and obtained the ratio 0·931, so that if the diffusion coeff. of radium emanation is 0·126, that of thorium emanation is 0·117. Assuming that the diffusion law is valid for the case of a minute proportion of the radioactive radiation, the mol. wt., x, is 1 : $(0.931)^2=1 : x$, or $x=0.867$ times less than that of niton. S. Russ measured the diffusion coeff. of thorium emanation in air and in argon at different press. He found for air :

p mm.	82·5	175	375·2	761·2
Diffusion coeff.	9·66	4·36	2·11	1·03
Product	79·7	76·3	79·4	78·8

Hence, the coeff. in argon at 760 mm. is 0·103, and in air, 0·087. M. S. Leslie noted that the value of the coeff. is modified by the form of the vessel, and she obtained in different vessels at 15° and 760 mm. press., 0·085, 0·115, and 0·111. It follows that there is not much difference in the coeff. of diffusion of thorium and radium emanations. The results are too uncertain to furnish reliable values for the at. wt. M. S. Leslie compared the effusion of thorium emanation, with that of oxygen, and obtained a mol. wt. approximately 200. On the assumption that the loss of an α-particle reduces the at. wt. of an element four units, the at. wt. of thorium emanation deduced from that of thorium is 232·4 less $3 \times 4 = 220·4$.

E. Rutherford and F. Soddy cooled the emanation admixed with a large proportion of gas, and found it liquefied at the temp. of liquid air. The influence of the velocity of the stream and nature of the admixed gas is very much the same as with radium emanation; A. Fleck, and S. Lorie noted small differences. According to the latter, the first trace of vaporization occurs at $-164°$; at $-150°$, about half the emanation is gaseous; and at $-125°$, no liquid is perceptible; but, on account of the small quantities available, it is very difficult to obtain accurate data. S. Kinoshita measured the properties of uncondensed gas at different temp. and press. The condensation temp. of thorium emanation appears to be 2° or 3° higher than with actinium emanation.

Thorium emanation emits α-rays which, according to O. Hahn, have a range of 5·5 cm. in air at 760 mm. and 15°; T. Barratt, and H. Geiger and J. M. Nuttall gave 5·00 cm. at 15°, and 4·74 cm. at 0°. Some of the older observations were made on samples contaminated with thorium-A. H. Geiger found the initial velocity calculated from $V^3 = aR$ to be $1·85 \times 10^9$ cm. per sec. at 0°—where V denotes the velocity; R, the range; and a, a constant. H. L. Bronson found that the emanation furnishes four α-particles for each α-particle furnished by the so-called active deposit from thorium emanation. The phenomenon was further studied by H. Geiger and E. Marsden, and M. S. Leslie, and it is taken to show that the decay of the emanation gives a very short-lived product—the so-called thorium-A. J. Satterly found that an atom of thorium emanation in passing into thorium-A loses one α-particle. According to J. M. W. Slater, thorium emanation emits soft β-rays—the so-called delta rays. E. Rutherford and F. Soddy found the half-life period of thorium emanation to be about one minute. C. le Rossignol and C. T. Gimingham gave 51 sec.; H. L. Bronson, 54 sec.; O. Hahn, 53·3 sec.; M. S. Leslie, 54·3 sec.; R. Schmid, 54·5 ± 0·03 sec.; and P. B. Perkins, 54·53 ± 0·041 sec. The average life period is 78·7 sec., and the radioactive constant $\lambda = 1·27 \times 10^{-2}$ sec. The formulæ of H. Geiger and J. M. Nuttall, R. Swinne, and H. A. Wilson, discussed in connection with radium, apply very well for the relation between the range, R, of the α-particles and the radioactive constant. G. H. Briggs studied the electric charge of the atoms of thorium emanation.

A. Klaus measured the absorption coeff. of thorium emanation in water and in petroleum, and found respectively $a = 1·052$ and 4·97. R. W. Boyle arranged the following liquids in the order of increasing solubility: cupric sulphate soln., calcium chloride soln., water, sulphuric acid, alcohol, and petroleum. The series is the same as for radium emanation, which, according to F. von Hevesy, indicates a close chemical relationship. E. Rutherford, R. W. Boyle, and G. von Hevesy studied the occlusion of thorium emanation by different varieties of wood and tar charcoal. Cocoa-nut charcoal was the strongest absorbent. R. W. Boyle found the partition coeff. at 18° is greater than 50. E. Rutherford and F. Soddy found that dil. or conc. acids and alkalies are without influence on thorium emanation; it is not perceptibly attacked by white-hot platinum, lead chromate, zinc dust, magnesium dust, platinum sponge, or platinum black. In these experiments, the emanation was always mixed with a large proportion of an inert gas, and in order to prove that the result is not due to a mere activation of the gas employed, carbon dioxide was passed over thorium oxide, air was then introduced, and the carbon dioxide removed by soda-lime. The results were the same in different

variations of the experiment. This shows the gaseous nature and the chemical inactivity of the emanation. S. G. Tracy, D. Minami, A. Bickel, and K. Kojo have studied the physiological action of thorium emanation.

When substances are exposed to thorium emanation they become radioactive, the so-called *induced radioactivity*. The induced radioactivity is due to the film of decay products of thorium emanation which is formed on the exposed surface. This product, for convenience, is called the *active deposit of thorium*. It is best obtained by exposing an insulated, negatively charged wire—110–220 volts—to the emanation, or in a vessel containing a preparation of thorium. After three days' exposure, the decay products are in equilibrium. The active deposit is a mixture of the successive decay products thorium (-A, -B, -C, and -D). The long-range particles—15·0 and 18·4 cm.—in addition to those of range 8·6 and 11·5 cm., were measured by L. F. Bates and J. S. Rogers. S. Rosenblum found the ratio of the speeds of the two groups of α-particles from the active deposit to be 1·209. Thorium-A is an ephemeral product with a very short half-life period—nearly one-eighth of a second. Thorium-B has a half-life period of about 10 hrs., thorium-C, about an hour. H. A. Erikson studied the mobility of the ions of the active deposits. The active deposit dissolves when boiled with acids.

L. Bronson found that twice as many α-particles were ejected by thorium emanation as were expelled from the active deposit of thorium ; and H. Geiger and E. Marsden noted that the particles from thorium emanation appeared almost as if they were double but with an average interval of $\frac{1}{5}$th sec. They hence inferred that the emanation must contain two α-ray products, one of which had an average life of $\frac{1}{5}$th sec. H. Geiger showed that the two α-particles have a different range. The ephemeral substance is non-gaseous, and is the first decay product of thorium emanation. It is called **thorium-A,** ThA. Prior to E. Rutherford and H. Geiger's observations, thorium-A represented the substance now known as thorium-B ; and the latter was thought to be the direct derivative of the emanation. The association of thorium-A with the emanation is due to the brevity of its life ; the greater part of it is transformed *in situ* before it has had time to diffuse to the surface of the containing vessel. When the emanation breaks down, an α-particle is ejected from the atom, and the residue forms an atom of thorium-A. E. Rutherford and H. Geiger showed that the atoms of thorium-A initially carry a positive charge, and are collected by concentration on a plate carrying an intense negative charge. Under ordinary conditions, thorium-A has all disappeared before the plate can be examined. Under ordinary conditions, therefore, thorium-A has to be very quickly examined along with the emanation. The product of the decay is thorium-B, and this quickly changes to thorium-C. In its decay, thorium-A emits α-radiations which H. Geiger and J. M. Nuttall found to have a range of 5·7 cm. at 15° in air—T. Barratt gave 5·4 cm.—the initial velocity is $1·80 \times 10^9$ cm. per sec. H. G. J. Moseley and K. Fajans found for the half-life period 0·145 sec., for the life period, 0·20 sec., and for the radioactive constant, $\lambda = 4·95$ secs. The at. wt. is taken to be 216. In its chemical nature thorium-A resembles tellurium ; and it appears to be isotopic with polonium. If an aq. soln. of thorium nitrate be treated with ammonia, thorium-A is precipitated along with the thorium ; and if the precipitate be treated with fumaric acid, thorium-A is dissolved. According to F. von Lerch, thorium-A is electrochemically a less rare element than its decay product thorium-B. If a nickel wire be dipped in a soln. of the active deposit of thorium, a radioactive deposit is obtained which contains no thorium-A ; if, however, the nickel wire be wrapped round with platinum wire, thorium-A is deposited on the platinum. G. H. Briggs studied the distribution of thorium-A in electrical fields.

E. Rutherford [5] found that a plate which has been exposed to constant supply of thorium emanation for several days acquires a radioactivity which decays slowly at first, but after a few hours, the rate of decay increases when the period is 10·6 hrs. whether the activity is measured by the α-, β-, or γ-rays. E. Rutherford and H. T. Brooks showed that with a plate which has had only a short exposure to the

emanation, the activity starts from nearly zero, and passes through a maximum after about 220 min., and then decays with a period as before. A negatively charged wire which has been exposed for about a second to thorium emanation, has little more than thorium-B. E. Rutherford showed that the observations accord with the assumption that **thorium-B,** ThB, does not emit α-rays and is transformed into thorium-C which emits α-, β-, and γ-rays. The active deposit of thorium thus contains a mixture of thorium-B and thorium-C. Thorium-B was initially called thorium-A; E. Rutherford and H. Geiger changed the name from thorium-A to thorium-B after the discovery of thorium-A. There are several methods of separating the two. J. M. W. Slater, and F. C. Gates showed that thorium-B is volatilized between 700° and 1000°, while thorium-C is not volatile under these conditions. The thorium-B can be sublimed on to a cold cylinder surrounding the electrically heated wire on which the active deposit has been collected. The actual temp. of volatilization was shown by F. von Lerch to depend to some extent upon the composition of the active deposit. According to S. Loria, the proportion of volatilization of thorium-B, formed from thorium emanation on platinum foil, at different temp. is given by

	650°	700°	750°	800°	850°	900°	950°	1000°	1100°
Per cent. ThB . .	0	8	40	73	82	90	94	97	100

T. Barratt and A. B. Wood also made some observations on this subject. S. Meyer found the volatilization of thorium-B from gold begins sooner than from platinum or palladium, and between 300° and 1000° is greater from gold than for the other two metals. F. von Lerch electrolyzed a soln. of the active deposit, and found that thorium-B is not so rare as thorium (-C and -D), so that the latter are deposited on the cathode while thorium-B remains in soln. According to F. Paneth and G. von Hevesy, like lead, thorium-B can be deposited electrolytically as a dioxide, $(ThB)O_2$, on the anode, and the element can be deposited on the cathode. G. von Hevesy and E. Rona showed that the anode deposit of thorium-B dioxide is less soluble in acids—nitric acid of various conc., and in nitric acid containing glycerol—than the cathode deposit. For a soln. of thorium-B, in presence of lead, deposition occurs with perceptible amounts of lead at —0·44 volt, but in absence of lead at —0·33 volt. The anodic deposition of thorium-B in absence of lead showed a sudden deposition between 1·0 and 1·1 vols., which is very near to that of lead dioxide. The thorium-B is deposited no longer as metal, but as dioxide. If a nickel plate be dipped in a soln. of the active deposit, thorium-B remains in soln., while thorium-C is precipitated. According to C. F. Hogley, thorium-B is more soluble in inorganic solvents, and less soluble in organic solvents than thorium-C. M. Levin also found that if lampblack be added to a mixed soln. of thorium-B and thorium-C, the latter is absorbed by the carbon, and thorium-B will be found in the soln. K. Horovitz and F. Paneth studied the adsorption of thorium-B by different salts and oxides. H. N. McCoy and C. H. Viol found that ferric iron precipitated by fumaric acid from a boiling soln. of thorium-B, carries down all the thorium-C, and only a small proportion of the thorium-B; by redissolving the precipitate, and repeating the process, it is claimed that thorium-C can be obtained in which no thorium-B can be detected. J. A. Cranston and co-workers showed that the ferric hydroxide adsorbs the thorium-B and thorium-C in proportions varying regularly with the soln., and to get a separation the acidity must be above a certain limit. The absorption is said to be a true adsorption effect, and not due to the formation of a chemical compound. A. Fleck discussed the isotopy of thorium-B and lead, and of thorium-C, radium-C, and actinium-C with bismuth.

The at. wt. of thorium-B is 212. F. von Lerch found that thorium-B is not a rayless product as was at first supposed by E. Rutherford, but it emits soft β-rays. F. von Lerch said that 28 per cent. of the total β-ray activity of the active deposit is due to thorium-B; while O. Hahn and L. Meitner estimated 43 per cent. Accord-

ing to O. von Baeyer and co-workers, the magnetic spectrum of the β-rays shows velocities of 1.89×10^{10} and 2.16×10^{10} cm. per sec., and for the latter an absorption coeff. in aluminium of 153 cm.$^{-1}$; O. Hahn gave 175 cm.$^{-1}$. D. R. Yovanovitch and J. d'Espine, and W. Pohlmeyer measured the magnetic spectrum of the rapid β-rays; D. H. Black, the magnetic spectrum of the β- and γ-rays. E. Rutherford and H. Richardson found 3 types of γ-rays with absorption coeff. in aluminium of 160 cm.$^{-1}$, 32 cm.$^{-1}$, and 0.36 cm.$^{-1}$. In its general properties, thorium-B resembles lead with which it is isotopic. G. von Hevesy found the diffusion coeff. to be 0.67 sq. cm. per day corresponding with a bivalent element. J. Groh and G. von Hevesy found the diffusion coeff. of thorium-B in lead to be 2.22 per sq. cm. per day at 343°. F. von Lerch, and H. N. McCoy and C. H. Viol found the half-life period to be 10.6 hrs.; J. E. Shrader gave 10.4 hrs. The corresponding average-life period is 15.3 hrs.; and the radioactive constant, $\gamma = 1.82 \times 10^{-5}$. The decay product of thorium-B is thorium-C. A. Piccard and G. Volkart found the rate of decay of thorium-B is not appreciably affected by a magnetic field of 83,000 gauss. K. Fajans and K. von Beckerath found that silver halides do not appreciably adsorb thorium-B, but in the presence of an excess of acid, adsorption proceeds proportionally with the conc. of the H·-ions. F. Paneth and co-workers found evidence of the formation of a **hydride** of thorium-B.

As indicated above, E. Rutherford inferred from the variation of the radio-activity of the active deposit of thorium with time, that an element with a half-life period is involved in the decay of the deposit. This element is called **thorium-C,** ThC; it is the direct decay product of thorium-B. The complex product here termed thorium-C was formerly regarded as a mixture of thorium-B and thorium-C. K. Fajans called thorium-C, thorium-C$_1$. M. Levin found that when a soln. of the active deposit is shaken for a short time with charcoal, thorium-C is absorbed, and most of the thorium-B remains in soln. S. Meyer studied the transformation of thorium-B to thorium-C. K. Horovitz and F. Paneth studied the adsorption of thorium-B and thorium-C by different oxides and salts. Oxides of copper, titanium, and tantalum adsorb thorium-C more readily than thorium-B. They found that, like bismuth compounds, salts of thorium-C are easily hydrolyzed in aq. soln. while salts of thorium-B resemble lead salts and are not readily hydrolyzed. F. von Lerch found that if nickel is dipped into a hot hydrochloric acid soln. of the active deposit, thorium-C is precipitated, and similarly when zinc is used in place of nickel. The electrolysis of the soln. also gives a deposit of thorium-C on the cathode, and the product is fairly pure. Thorium-X if present is not deposited. F. Paneth, and G. von Hevesy found that the amount of thorium-C deposited from a $0.01N$-nitric acid soln. on a platinum plate, kept at a constant voltage of 0.6 with reference to a normal calomel electrode, is greatly reduced if a few milligrams of bismuth be present. For thorium-C in the presence of bismuth, there is a sudden increase in the decomposition potential at —0.08 volt, an immersed bismuth plate shows a potential of 0.082 volt. They recommended generally that when the separation of one radio-element from another in a high state of purity is desired, the addition of an appreciable quantity of an element isotopic with the other element—for example, in the separation of pure thorium-C from thorium-B, lead should be added, the action being analogous to the prevention of adsorption of uranium-X, for example, by the presence of thorium. G. von Hevesy and E. Rona measured the rate of soln. of mixtures of thorium-B and thorium-C in water, nitric acid of various conc., and in nitric acid containing glycerol. They found that the rate of soln. of molecularly thin layers of the radioactive elements follows the same laws as for layers of finite thickness. H. N. McCoy and C. H. Viol found that when the soln. of the active deposit of thorium is treated with fumaric acid according to H. Schlundt and R. B. Moore's process, the thorium-B remains in soln. while thorium-C is precipitated with iron—*vide supra*, thorium-B. J. M. W. Slater, and F. C. Gates showed that thorium-B is more readily volatilized than thorium-C, between 700° and 1000°, and this furnishes a convenient means of separation. S. Loria showed that an

electro-deposited mixture or a mixture obtained by the evaporation of mixed soln. is more readily separated than the active deposit derived from the emanation. The percentage of thorium-C volatilized from the active deposit and from the electro-deposit at different temp. was found to be :

	700°	750°	800°	900°	950°	1000°	1100°	1200°	1300°
Electro-dep. . .	0	0	0	5	20	32	70	93	98
Active dep. . .	0	15	21	33	40	70	95	100	—

S. Meyer found that the volatilization of thorium-C from gold is very similar to that from platinum ; and in both cases there is a discontinuity in the volatilization curve at 760° which is due to the formation of an oxide of thorium-C which is stable at this temp. The discontinuity is not shown with the volatilization of thorium-C from palladium. From T. Godlewsky's work it appears that recoil particles are driven from the active deposit into the metal from the emanation, but not from the electro-deposited or evaporation film. Thorium-C chloride is much more volatile than thorium-B chloride ; it begins to volatilize at 100°.

The at. wt. of thorium-C is 212. The element is isotopic with bismuth. W. Metzener found that the quantitative separation of thorium-C by means of nickel foil in a boiling hydrochloric acid soln. is hindered by the presence of bismuth, but the fraction of the radio-element precipitated on the foil is the same as the fraction of the bismuth also precipitated. Similarly, the volatilization is stopped if bismuth oxide is present. Precipitation of thorium-C by silver chloride or bromide is prevented by addition of bismuth. The proportion of thorium-C in the precipitate and filtrate is shown to be the same as that of the bismuth when the latter, in presence of thorium-C, is fractionally precipitated (i) as oxychloride, (ii) as bismuth magnesium nitrate, and (iii) as basic bismuth nitrate. G. von Hevesy found the diffusion constant to be 0·5 sq. cm. per day, corresponding with a ter-valent element. E. Rutherford found approximately 55 mins. for the half-life period ; G. B. Pegram, 60 mins. ; and F. von Lerch, 60·48 ± 0·035 mins. H. N. McCoy and C. H. Viol found 60·8 mins. for the half-life period, 87·7 mins. for the average-life period, and $1·90 \times 10^{-4}$ secs. for the radioactive constant λ. Thorium-C emits a- and β-rays. D. H. Black studied the magnetic spectrum of the γ-rays from thorium-C. L. Meitner found the a- and β-ray change of thorium-C to be free from γ-rays. W. Pohlmeyer, and D. H. Black studied the magnetic spectrum of the β-rays of thorium-C. W. Kolhörster showed that the average range of recoil atoms of thorium-C in hydrogen is 0·553 mm. at 15° and 760 mm., and for thorium-C₁, 0·963 mm. ; the corresponding values in air are respectively 0·129 mm. and 0·224 mm. L. Myssowsky studied the kinetic energy of the a-particles from thorium-C. O. Hahn's measurements of the range of the a-particles showed that two groups are present, one with a range of 8·6 cm., and the other with a range of 5 cm. E. Marsden similarly obtained 8·6 and 4·8 cm. It was at first concluded that two successive a-ray products were present, but O. Hahn and L. Meitner, and H. Geiger and E. Marsden observed no signs of any separation of the two by recoil. H. L. Bronson, and H. Geiger and E. Marsden showed that for three particles emitted by thorium emanation in equilibrium with the active deposit, only one was contributed by thorium-C, and since only three a-ray products are involved in the phenomenon—the emanation, thorium-A, and thorium-C, it follows that the a-particles from thorium-C correspond with but one product in equilibrium with the emanation. Besides a-particles with ranges 5·0 and 8·6 cm., about 1 in 10,000 has a range 11·3 cm. E. Rutherford showed that the last-named rays are emitted from the source, and are not a secondary product of bombardment. F. L. Bates and J. S. Rogers found in addition some particles of range 15·0 and 18·4 cm. are given off, and that the relative numbers of the particles 8·6 cm., 11·5 cm., 15·0 cm. and 18·4 cm. are 10^6, 220, 47, and 15 respectively. The energy differences for 8·6–11·5 cm. being $2·99 \times 10^{-6}$ ergs ; 11·5–15·0 cm., $3·29 \times 10^{-6}$ ergs ; and 15·0–18·4 cm., $2·99 \times 10^{-6}$ ergs. D. R. Yovanovitch and J. d'Espine measured

the magnetic spectrum of the rapid β-rays. E. Rutherford found that the mass of the α-particles from thorium-C is 4, not 3. A. G. Shenstone and H. Schlundt found the ratio of the number of α-particles emitted by thorium-C and radium-C to be 0·75. W. D. Harkins and R. W. Ryan studied photographically the tracks of the α-rays. F. Paneth and co-workers obtained a **hydride** of thorium-C by the action of magnesium or zinc powder on soln of the salts.

E. Marsden and T. Barratt found that the α-particles of range 5·0 and 8·6 cm. from thorium-C are not equal in number, since 65 per cent. had the longer range and 35 per cent. the shorter range. Hence, thorium-C breaks up in two distinct ways. The component furnishing the α-rays of range 4·8 cm. is called thorium-C_1 or **thorium-D,** ThD, and that component with α-rays of range 8·6 cm. is called **thorium-C_2,** ThC$_2$. These two components always appear together in constant ratio approximately thorium-C_2 : thorium-D=2 : 1. The at. wt. of thorium-C_2 is about 212 ; it emits α-rays only. A. B. Wood obtained 4·95 cm. for the range of the α-particles of thorium-C_2 and the velocity $1·714 \times 10^9$ cm. per sec. ; for thorium-C_2, the α-particles of range 8·6 cm. have a velocity $2·06 \times 10^9$ cm. per sec. E. Rutherford and A. B. Wood, also made observations on this subject. E. Marsden and C. G. Darwin, and O. Hahn and L. Meitner could not separate by the recoil method the two components derived from thorium-C. They found thorium-C emitted β-rays of greater penetrating power than those from thorium-D ; but thorium-C gave out little if any γ-rays in comparison with those from thorium-D. The α-ray transformation of thorium-C was assumed to give rise to thorium-D, which breaks up with the emission of β- and γ-rays ; the β-ray transformation of thorium-C was assumed to furnish thorium-C_2, which breaks up emitting the α-rays of range 8·6 cm. G. H. Henderson obtained 8·167 cm. The transformations are thus symbolized :

$$\text{ThA} \rightarrow \text{ThB} \rightarrow \text{ThC} \Big\langle {\text{ThD} \rightarrow ? \atop \text{ThC}_2 \rightarrow} ; \quad \text{or} \quad \text{ThC} \Big\langle {\text{ThC}_1 \rightarrow \text{ThD} \rightarrow \atop \text{ThC}_2 \rightarrow}$$
This view is in harmony with H. Geiger and J. M. Nuttall's relation between the period of the transformation and the range of the α-particles. L. Meitner partially separated the two components of thorium-C. E. Marsden and C. G. Darwin obtained the ratio Th-C : Th-C_2=0·35 ; E. Albrecht also studied this subject. Thorium-B was obtained by evaporating the slightly acid soln. of the active deposit to dryness after boiling it first with nickel foil, and the α- and γ-radiations from this preparation increased with time similarly, the curves running parallel. If before treatment with nickel, stannous chloride be added to the soln., the α-rays from the evaporated soln. increase much less than the γ-rays, and attain their maximum somewhat earlier. The range of the α-rays of thorium-C_2 shows that the period must be of the order of 10^{-12} sec. so that the non-parallelism of the α- and γ-curves shows that the two C-members cannot stand in direct genetic connection, and that thorium-D cannot be the product of both, for then the α- and γ-curves must necessarily be practically parallel. When stannous chloride is added, at least part of that one of the two C-members which does not give thorium-D must remain in soln. instead of being precipitated by the nickel. The β-rays of thorium-C have velocities $2·79 \times 10^{10}$ and $2·85 \times 10^{10}$ cm. per sec., and an absorption coeff. in aluminium of 14·4 per cm. The at. wt. of thorium-C_2 is 212, the half-life period is about 10^{-11} sec., the average-life period about 10^{-11} sec., and the radioactive constant about 10^{11} secs. For the mobilities of the gas ions, *vide* thorium-D.

The α- and β-rays from the active deposit of thorium were at first attributed to the thorium-C, but O. Hahn and L. Meitner showed that these rays were derived from a decay product of thorium-C which was named **thorium-D,** ThD. This product is best separated from thorium-C by the recoil method on a negatively charged·plate exposed a short distance above a film of the active deposit. According to A. B. Wood, the recoil particles from thorium-C chloride are not thorium-D chloride, but thorium-D. O. Hahn and L. Meitner also separated thorium-D by

entraining it with precipitates formed with hydrogen sulphide, or by adding charcoal to a soln. of the active deposit. F. von Lerch and E. von Wartburg electrolyzed an acid soln. of the active deposit of thorium, using a feeble current (0·6 milliamp.) and platinum electrodes 1 cm. apart. Thorium-D was deposited on the cathode; it was washed successively with water, alcohol, and ether. It is also precipitated by introducing a plate of nickel into the soln. Thorium-D is electrochemically less noble than thorium-C, and in conc. acids it is less soluble than thorium-B and thorium-C. Thorium-D is easily separated from thorium-A, -B, and -C by heating; and at a red-heat, it is more volatile than thorium-B. According to A. B. Wood, it volatilizes at 520°, and is completely evaporated at 700°. Thorium-D chloride volatilizes at 270°.

Thorium-D has an at. wt. about 208; and it is derived from thorium-C. It emits no α-rays but gives off β- and γ-rays. O. von Baeyer and co-workers found the magnetic spectrum of the β-rays to furnish rays with initial velocities 0·87, 1·08, 2·79, $2·85 \times 10^{11}$ cm. per sec. J. Franck determined the mobility of the radioactive ions of thorium-D in air, nitrogen, and hydrogen. The ions of thorium-D were obtained by the use of plates on which thorium-A, -B, and -C had been deposited by exposing the negatively charged plates to the influence of the emanation of a radio-thorium preparation. The mobility of the positively charged thorium-D atoms is approximately equal to the mobility of the positive gaseous ions in air, nitrogen, and hydrogen. This leads to the conclusion that the gas ions are complex molecular aggregates. The absorption coeff. of the β-rays for aluminium is 21·6 cm.$^{-1}$, those from thorium-C have the absorption coeff. 14·4 cm.$^{-1}$. A. B. Wood found the relative intensities of the β-rays from thorium-C and thorium-D to be as 1·5 : 1. E. Rutherford and H. Richardson gave the absorption coeff. of the γ-rays as 0·096 cm.$^{-1}$ for aluminium; F. and W. M. Soddy and A. S. Russell found for lead, 0·462 cm.$^{-1}$, and they also measured the absorption coeff. for copper, brass, iron, tin, zinc, and aluminium. The half-life period is 3·1 mins. and the average-life period is 4·47 mins.; the radioactive constant is $3·73 \times 10^{-3}$ sec. E. Albrecht gives 3·20 mins. for the half-life period, and $3·61 \times 10^{-3}$ sec. for the radioactive constant. According to W. Metzener, thorium-D forms mixed crystals with thallous nitrate, carbonate, and ammonio-sulphate. The proportion of thorium-D in the crystals and mother-liquor was the same, no separation or conc. being possible. Thorium-D is isotopic with radium-C_2, and actinium-D. C. D. Ellis measured the wave-length of the γ-rays from thorium-D; and D. H. Black, their magnetic spectrum.

A summary of the radioactive properties of the members of the thorium series is given in Table III. The relation between the range and the radioactive constant

TABLE III.—PROPERTIES OF THE THORIUM FAMILY OF RADIOACTIVE ELEMENTS.

FIG. 4.—Arrangement of the Thorium Decay Products in the Periodic Table.

elements of the series on the assumption that the at. wt. of the members of the descendants of thorium follow the displacement rule, the positions of the members of the series in the periodic table are shown in Fig. 4. G. Kirsch assumes that the parent of thorium is a uranium isotope present in small amounts in terrestrial uranium at the time the oldest uranium minerals were formed, and which has since completely disappeared. W. Riss also discussed the genetic relations of thorium and uranium.

The nature of the end-product of the transformation of thorium is unknown. The next derivative of thorium-D has been called **thorium-E,** or **thorium-lead.** It

is suggested by A. Holmes and R. W. Lawson that the end-product may be a stable isotope of lead—with a half-life period of 10^6 years ; and that the lead contents of a thorium-uranium mineral originally free from lead should owe its lead to the disintegration of both thorium and uranium. They conclude that thorium-E is an unstable isotope of lead, and that thorium-E must gradually disintegrate losing radiations which have so far eluded detection, and becoming transformed into a simpler element. If thorium-lead evolves β-rays, the result would be an isotope of bismuth. Starting from thorium with its at. wt. 232·12, there are six α-ray products. This would furnish an element with an at. wt. of 232·12 less 6×4, or 208·12. This suggests that bismuth, at. wt. 208·12, is the end-member of the series. The rate of transformation of thorium is about one-fifth of the rate of transformation of uranium, and, assuming that lead is the end-product of the uranium-radium series, then, since the ratio Pb/U is about 0·20, the ratio Bi/U should be about 0·04. Assuming that the methods of analysis are reliable enough to furnish the desired information, E. Rutherford has shown that the amount of bismuth actually observed in minerals is far too small to support this hypothesis. It has also been suggested that the further decay of thorium bismuth might furnish an isotope of thallium, but the evidence from analyses of the minerals is not sufficiently.decisive.

§ 4. The Preparation and Properties of Thorium

The element thorium has not been obtained of a high degree of purity. This is partly due to the high m.p. of the metal, and to the ease with which it unites with hydrogen, oxygen, nitrogen, and carbon. J. J. Berzelius [1] obtained the impure metal by heating a mixture of potassium with potassium thorium fluoride or chloride, or thorium chloride in a glass tube; the act of decomposition was attended by a feeble explosion. The metal appeared as a grey powder. J. J. Chydenius used sodium in place of potassium. C. A. Matignon and M. Delépine said that with thorium chloride and sodium, the product contains 74 per cent. of thorium, and much thoria. L. F. Nilson heated to redness a mixture of sodium with a mol of thorium chloride and two mols of potassium chloride contained in alternate layers in an iron cylinder. The product was washed successively with water, alcohol, and ether. The product contained 20 per cent. of thoria as impurity. W. von Bolton heated in a crucible a mixture of thorium chloride with sodium and covered it with a layer of potassium chloride. The product was washed with alcohol to remove the sodium, then with cold and with boiling water, boiling dil. nitric acid, and finally with water. The powdered metal was hammered into a thick-walled copper tube 10 mm. in diameter; and this was rolled into 1 mm. wire. The copper was dissolved by dil. nitric acid, and a spongy wire of thorium was obtained. This was rolled into a coherent strip. W. von Bolton, P. Askenasy, and H. Karstens considered their product to be free from oxide; but R. J. Meyer claims that oxide must have been present. H. Moissan and O. Hönigschmid, and C. A. Matignon and M. Delépine prepared thorium chloride free from oxychloride, and reduced it with sodium both in air, and in vacuo, but they were unable to obtain a metal with less than 3 per cent. of oxide. E. Chauvenet heated to 600° a mixture of one mol of thorium chloride with four gram-atoms of lithium or sodium contained in an iron boat in a quartz tube, taking precautions to prevent the ingress of air. The product contained 3·2 per cent. of thoria. If a nickel boat be used, a nickel-thorium alloy is formed. D. Lely and L. Hamburger distilled sodium and thorium chloride into an exhausted steel cylinder, and heated the mixture to 700°. The product contained 1 per cent. of the oxide. The metal was compressed into a rod, and an alternating current passed through it in a vacuum furnace. The particles sintered together, and formed a compact metal.

Neither J. J. Berzelius, nor C. Bergemann was able to reduce thorium oxide by the alkali metals. O. Ruff and H. Brintzinger found that sodium at 900°– 950° has very little action on thoria, but with calcium there is a 62 per cent. yield of the metal; and with a sodium-calcium alloy, an 84 per cent. yield of thorium. C. Winkler tried to reduce the oxide by heating it with a 20 per cent. excess of magnesium in an evacuated tube, but the product was a mixture of magnesium and thorium with the oxides of the two metals. H. Kuzel and E. Wedekind reduced thoria by means of calcium. C. A. Matignon and M. Delépine also obtained an impure product by the action of magnesium or aluminium on the oxide. H. Goldschmidt and C. Vautin tried the thermite reaction with aluminium powder and thorium oxide, and found beads of thorium in the sintered mass. K. A. Kühne claimed to have obtained reguline thorium by adding some chlorate or perchlorate to the mixture in H. Goldschmidt's process. L. Troost fused a mixture of thorium carbide and oxide and obtained the impure metal. According to H. Moissan and A. Étard, when thoria is heated in the electric furnace with a sufficient quantity of sugar carbon, it yields a crystalline carbide; when less carbon is employed, a fused mass is produced, consisting of an alloy of thorium and thorium carbide. H. C. Greenwood said that the reaction begins at about 1600°. O. Hönigschmid heated a mixture of thorium oxide and silicon in the electric arc furnace and obtained thorium silicide.

E. W. von Siemens and J. G. Halske proposed to remove the oxide by making the thorium form a fusible alloy with tin, lead, zinc, cadmium, copper, or aluminium; they also heated the thorium with tantalum or another metal of the vanadium family which reduces the thoria to metal. When strongly heated, the tantalum pentoxide volatilizes before the thorium. E. Chauvenet prepared thorium by heating thorium hydride under 10 mm. press.; E. W. von Siemens and J. G. Halske claimed to make thorium by heating, in the absence of air, thorium nitride or a compound of thorium with another element of the nitrogen family. If the nitride be shaped into a rod, and then heated with absence of air by an electric current, a coherent metal is formed. They also obtained thorium from the sulphide. E. W. von Siemens and J. G. Halske also obtained thorium by distilling sodium and thorium acetylacetonate through a red-hot tube.

H. Moissan and O. Hönigschmid did not succeed in preparing thorium of a high degree of purity by electrolytic processes. They electrolyzed potassium thorium chloride contained in a covered porcelain crucible at about 600°, using graphite electrodes, and an atm. free from oxygen. The porcelain vessels were always attacked, and the appearance of the metal, which is often obtained in definite crystals, indicates that the oxide contained in the bath becomes, in some way, mechanically interposed between the particles of metal at the moment of their deposition. H. von Wartenberg electrolyzed a mixture of thorium chloride and sodium or potassium chloride in a graphite crucible at 800°; graphite electrodes were used. The yield was 40 per cent., and the product contained 88·2 per cent. of thorium; 11·6 of thoria; 0·04, sodium; 0·03, silicon; 0·06, iron; and 0·15, carbon. A. Duboin said that the use of potassium fluoride gives no better results. E. Chauvenet proposed using rubidium thorium chloride. H. von Wartenberg reduced thoria in the electric furnace by hydrogen at 5 atm. press. in the presence of a metal like tungsten to dissolve the reduced thorium. G. Siebert and E. Korten prepared the metal by heating the halides to a high temp. in the presence of reducing agents—e.g. carbon; and A. E. van Arkel and J. H. de Boer, by passing the vapour of the tetrahalide over a heated tungsten filament—vide titanium.

According to E. Wedekind, and H. Baumhauer, **colloidal thorium** is made by rubbing in a mortar finely divided thorium with cold dil. acetic acid. If a stronger acid be used, the metal is acted upon. The paste is brought on to a filter, and the acetic acid washed out with cold water. At a certain point, a colloidal soln. passes through. It shows grey opalescence by reflected light, and appears brown when light is transmitted through it. The hydrosol of thorium is fairly stable in the

presence of certain electrolytes, but the alkalies readily bring about its precipitation, presumably because of decomposition of thorium acetate, which exerts a protective action on the colloid. It is stable against mineral acids. Freezing invariably brings about coagulation, the precipitate being readily observable on thawing. A freshly dialyzed colloidal thorium soln. was examined in an electrolytic cell. It was free from electrolytes. The space round the anode rapidly became clear when a difference of potential of 18 volts was set up between the electrodes, the particles moving to the cathode. Colloidal thorium, therefore, like colloidal zirconium, carries a positive charge. In a very dil. soln. particles can be resolved ultramicroscopically. They appear to be colourless, and smaller than those of zirconium; and to be in violent commotion. A comparison of the radioactivities of thorium as metal and as hydrosol showed that 0·0235 of the latter were eq. to 0·111 of the former. It is remarkable and not explained that although metallic thorium has a radioactivity of 15·4 uranium-potassium-sulphate units, and that of thorium oxide prepared from it is 8·6, yet that of the thorium hydrosol is smaller than that of thorium nitrate soln. The gel dried in a high vacuum, and at a high temp., was found to contain thorium 20·5 per cent., and thorium oxide 78 per cent.

The physical properties of thorium.—The thorium prepared by J. J. Berzelius was described as a dark, lead-grey powder, which when pressed in an agate mortar assumed an iron-grey **colour,** and a metallic lustre. L. F. Nilson said that thorium is a dark grey, shining powder which under the microscope appears to consist of small six-sided plates. The thorium obtained by W. von Bolton was described as microcrystalline before it was rolled; and the rolled metal was said to have the colour of platinum. H. von Wartenberg also described his product as crystalline. W. C. Brögger described the **crystals** as octahedrons, and C. F. Rammelsberg, and A. E. Nordenskjöld said that they are isomorphous with zirconium; and J. Herzfeld and O. Korn said that they are isomorphous with silicon and the diamond. P. T. Cleve said they are not isomorphous with any known element; and P. Groth added: *Ob eine Isomorphie mit dem Zirkonium besteht, ist, wie die Krystallform des letzteren, unbekannt.* A. W. Hull, and H. Bohlin found the **X-radiogram** of thorium corresponds with a face-centred cubic lattice with side 5·04 A., and the shortest distance between the atoms 3·54 A. The X-radiogram was also examined by J. Böhm and co-workers, J. E. van Arkel, and V. M. Goldschmidt and L. Thomassen.

L. F. Nilson gave 10·968 for the **specific gravity** of amorphous and matt thorium, and 11·230 for the crystals; W. von Bolton gave 11·32 for the powder and 12·16 for the rolled and heated metal; and K. Honda gave 11·3. Some low values for the sp. gr.—*viz.* 7·35 by C. Bergemann; 7·657–7·795 by J. J. Chydenius; and 10·78 by L. F. Nilson—refer to mixtures of the metal with oxide. L. F. Nilson makes the at. vol. 20·94, and B. D. Steele has discussed the relation of the at. vol. to that of other metals. H. Moissan and A. Étard say that the metal is hard, and that it scratches glass but not quartz, and when struck with steel, it gives sparks. A. E. van Arkel and J. H. de Boer obtained ductile thorium by their mode of preparation. S. Dushman and I. Langmuir discussed the **diffusion** of thorium in tungsten. E. W. von Siemens and J. G. Halske say that thorium can be drawn into wire. L. F. Nilson gave 0·2757 for the **specific heat,** between 0° and 100°; and 6·41 for the at. ht. J. Dewar gave 0·0197 for the sp. ht. between the b.p. of hydrogen and nitrogen. L. F. Nilson said that the metal does not melt in the wind furnace, nor when burnt in oxygen. G. N. Lewis and co-workers, and E. D. Eastman gave, respectively, 13·6 and 12·4 Cals. per degree for the **entropy** of thorium at 25° and atm. press. W. von Bolton estimated the **melting point** to be near 1450°; and K. Honda gave 1450°. H. Moissan and O. Hönigschmid said that the metal does not melt at 1400°. H. von Wartenberg, however, said that the impure metal melts at 1690°, but if it were quite free from carbide, the m.p. would be over 1700°; and W. Guertler and M. Pirani estimate the m.p. to be over 1800°. W. R. Mott gave 1450° for the m.p., and estimated 2800° for the

boiling point; and J. J. van Laar, 1840°. The latter also calculated for the **critical temperature,** 2940°, and for the **critical pressure,** 330 atm. F. Born estimated that the degree of dissociation of thorium oxide at 2000° is 10^{-27}, and at 3000°, about 6×10^{-6}.

R. Bunsen[2] said that purified thorium chloride gives no **flame spectrum,** nor does it show a spectrum with a feeble spark. W. Muthmann and C. Baur found that the purified thoria, and thorium sulphate give a pale blue light but no lines in the spectrum. H. Auerbach found only a continuous spectrum when thorium compounds are introduced into flames; while G. Meyer detected 0·01 mgrm. per c.c. by the spectral lines λ=4391·30 and 4382·10. The **spark spectrum** of thorium has been studied by R. Thalén, J. M. Eder and E. Valenta, A. G. G. Leonard, F. Exner and E. Haschek, R. Bunsen, O. Lohse, A. Hagenbach and H. Konen, R. J. Lang, J. N. Lockyer, etc. R. Thalén observed the lines 4273, 4278, 4281, 4382, and 4393 in the violet; 4864 in the blue; 4919, 5375, 5446, 5537, 5640, and 5699 in the green. The **arc spectrum** has been studied by J. M. Eder and E. Valenta, F. L. Cooper, F. Exner and E. Haschek, A. Hagenbach and H. Konen, C. E. Gissing, etc. The more intense lines are 3188·20, 3511·76, 3741·36, 4019·29, 4382·02, 4391·29, 4752·62, 4863·38, 4919·99, 5017·39, 5049·93, 5989·20, and 6462·83. W. J. Humphreys studied the effect of press.; B. E. Moore, the effect of a magnetic field, the so-called **Zeeman effect;** and R. J. Lang, the ultra-violet spectrum. Many of the lines are unsymmetrical in intensity and sharpness, the stronger component is a little displaced in the magnetic field, and some of the lines change their appearance without being separated. W. Ritz has discussed this subject. The line structure has been studied by P. G. Nutting. Thorium salts are colourless, and show no visible **absorption spectrum.** According to W. W. Coblentz, thoria gives no marked emission bands. The emissivity above 7μ is nearly as great as that of a perfect radiator. The high frequency or **X-ray spectrum** has been examined by D. Coster, V. Dolejsek, H. Bohlin, and M. Siegbahn and E. Friman. W. Duane and co-workers, and M. Siegbahn and E. Jönsson measured the K-series. B. B. Ray, M. de Broglie, W. Duane and co-workers, D. Coster, and M. Siegbahn gave for the L-series in Angström units, a_3a'=0·96524; a_1a=0·95342; $\beta_1\beta$=0·76259; $\beta_2\gamma$ =0·79108; $\gamma_1\delta$=0·65103; ϵ=1·11241; $\beta_5\zeta$=0·76259; $\beta_4\nu$=0·789; $\beta_3\psi$=0·7521; β_6=0·8262, and γ_6=0·6301. E. Hjalmar, G. Wentzel, and P. A. Ross gave for the M-series, a'=4·413; a=4·12915; β=3·9333; γ=3·6565; δ=3·127; and ϵ=3·006; D. Coster gave M_I=3·721; M_{II}=3·552; M_{III}=3·058; M_{IV}=2·571; and M_V=2·388. P. A. Ross also measured the M-series of lines. For the N-series, V. Dolejsek gave N_7P_1=9·310; N_7P_2=9·427; N_7O_3=11·462; N_6O_2 11·542; N_5O_1=13·255; N_5O_2=13·181; and N_5P_3=13·111. D. Coster also studied the N-series; K. Teucke, the radiation produced when thoria is bombarded by **cathode rays;** G. Fournier, the absorption of X-rays; and S. Dushman and co-workers, and H. R. Robinson, the **emission of electrons** by thorium. The **radioactivity** of thorium is discussed in a special section. G. Bardel said that if no uranium be present thorium compounds do not affect a photographic plate. H. K. Onnes found that, like lead and mercury, thorium becomes a super-conductor at low temp. R. Hamer discussed the **photoelectric property.** W. von Bolton gave 0·401 for the sp. **electrical resistance** of thorium. R. Berthold studied the relation between the photographic and ionizing effects of X-rays from thorium. J. W. Marden and co-workers studied the electrodeposition of thorium from soln. of thorium hydroxide in fluoboric or hydrofluosilicic acid. K. H. Kingdom and I. Langmuir studied the spluttering of thorium from a filament by a-rays. A. Heydweiller gave 23·5 for the **speed of migration,** $V°$, of the thorium cation, where $V=n\lambda$, when n denotes the transport number, and λ the eq. conductivity at 18°. B. Neumann and H. Richter found the **electrode potential** of thorium in thoric chloride 1·747 volts at 18°. Thorium is para-magnetic. K. Honda[3] gave 0·177 $\times 10^{-6}$ for the sp. **magnetic susceptibility**

of powdered thorium; and he found the value increases rapidly up to 400°. S. Meyer gave 416×10^{-6} for the atomic magnetism.

The chemical properties of thorium.—W. Ramsay and J. N. Collie [4] found that neither **helium** nor **argon** is absorbed when thorium is obtained by heating thoria with magnesium in an atm. of these gases. C. A. Matignon observed no signs of combination of argon with thorium. C. Winkler noted that a thorium hydride is formed when thorium oxide is reduced by magnesium in an atm. of **hydrogen.** The analyses corresponded with ThH_2, but the product was very impure. C. A. Matignon heated thorium in a tube in a stream of hydrogen, and found the two elements unite vigorously with the evolution of light. E. Chauvenet also found that lithium hydride, LiH, at 600°, reacts with thorium chloride. In both cases, **thorium hydride,** ThH_4, is produced. C. A. Matignon and M. Delépine gave for the heat of formation $Th + 2H_2 = ThH_4 + 42 \cdot 8$ Cals. E. Chauvenet gave for the dissociation press. in mm.:

	282°	299°	328°	350°	367°	381°	384°	387°	390°
Press.	160	242·5	300	500	624	672	705	740	760

Externally, thorium hydride looks like thorium except that it is a little darker, and rather more matte. When heated in vacuo, it furnishes thorium and hydrogen. It explodes when heated in a small tube in the presence of air. It burns in oxygen; chlorine does not immediately attack it at ordinary temp.; it is not decomposed by water; and hydrochloric acid attacks it—especially if heated. A. Klauber and J. M. von Mellenheim prepared what they regarded as a volatile thorium hydride by the action of water or dil. acids on magnesium thoride—best at 15°–20°. When passed through a heated glass tube, a ring of thorium was produced which is first brown and then grey, indicating two forms of thorium. It was said that the gas is unstable; the composition was not determined; the radioactivity is slight; and it can be condensed by liquid air. R. Schwarz and E. Konrad denied the existence of the gaseous hydride, and said that the deposits in the heated tube are derived from the hydrides of sulphur, phosphorus, and silicon. E. Chauvenet [5] found that the thorium at ordinary press. is not oxidized in **air** or in **oxygen;** but with higher press., the metal may be oxidized. N. B. Pilling and R. E. Bedworth studied the oxidation of thorium. L. F. Nilson said that the metal is stable in air at 120°, but H. Moissan and A. Étard found that the metal ignites when heated in air just below redness, and it burns brilliantly, forming the oxide and throwing out showers of incandescent sparks. The finely powdered metal ignites when rubbed or crushed. J. J. Berzelius, and J. J. Chydenius also noted that the powdered metal burns brilliantly in an alcohol flame; L. F. Nilson, and W. von Bolton observed similar results with Bunsen's flame. When heated in oxygen, the metal burns with blinding brilliancy. H. Moissan and A. Étard found the metal ignites when thrown on molten potassium chlorate. L. F. Nilson said that **water** does not act on the metal; but, according to H. Moissan and A. Étard, if 7 for 8 per cent. of carbide is present, the metal is slowly attacked, and a mixture of hydrogen, methane, acetylene, ethylene, and their homologues is slowly evolved.

L. F. Nilson showed that when thorium is heated in **chlorine,** the two elements unite vigorously with incandescence, and with the formation of thorium chloride; H. Moissan and A. Étard said that the reaction begins below a dull red heat. L. F. Nilson, and H. Moissan and A. Étard also found that analogous results are obtained with **bromine** and **iodine.** According to J. J. Berzelius, thorium is not changed when treated with **hydrofluoric acid,** but with **hydrochloric acid** the reaction is slow in the cold and fast when hot—hydrogen is evolved. W. von Bolton found that about 15 per cent. of a grey residue remains unattacked when hydrochloric acid acts on thorium, and this residue is transformed by nitric acid into a lemon yellow product. R. J. Meyer said that the residue is thoria; H. Karstens said that it is not thoria.

J. J. Berzelius, L. F. Nilson, and H. von Wartenberg noted that when thorium

is heated with **sulphur** the two elements react vigorously and with incandescence, forming thorium sulphide.	H. Moissan and A. Étard said that the reaction begins at a red heat; with **hydrogen sulphide,** thorium sulphide is formed without incandescence.	L. F. Nilson, and W. von Bolton found that **sulphuric acid** slowly attacks thorium; and, according to the former, with the evolution of sulphur dioxide.	J. J. Chydenius said that hot dil. sulphuric acid attacks thorium rapidly; and J. J. Berzelius, that the action begins rapidly with the evolution of hydrogen, and then becomes very slow.	C. A. Matignon and M. Delépine found that when thorium is heated with **nitrogen,** thorium nitride is formed.	J. J. Berzelius said that **nitric acid** attacks thorium only during a prolonged heating; J. J. Chydenius, that the action is rapid; L. F. Nilson, that neither conc. nor dil. nitric acid attacks thorium; and W. von Bolton that no perceptible action occurs with the boiling acid.

R. Escales found that thorium reduces many **metals** and metalloids from their compounds—e.g. phosphorus.	J. J. Berzelius, and L. F. Nilson reported that soln. of the **alkali hydroxides** have no perceptible action on thorium, and W. von Bolton, that no action occurs with the boiling alkali.	In its typical compounds thorium is quadrivalent, forming the oxide, ThO_2, and salts of the type ThX_4, where X is univalent.	Unlike most members of the family group, thorium does not act as an acidic oxide.	The colourless thorium salts are more stable in soln. than the corresponding ceric salts.	The high basicity of thorium in comparison with the other members of the family corresponds with a much smaller tendency to form complex salts.	A. Korczynsky studied the catalytic action of thorium and its salts on the hydrogenation of aromatic hydrocarbons; and W. W. Russell and H. S. Taylor, the promotor action of thoria on nickel catalysts.

Very few alloys of thorium have been prepared.	W. Kettembeil [6] could not prepare *thorium amalgam* by electrolyzing a soln. of a thorium salt using a mercury cathode.	O. Hönigschmid obtained an alloy with aluminium as a by-product in making aluminium silicide.	He reported the formation of a definite compound, **thorium trialuminide,** $ThAl_3$, from a mixture of the double fluoride of thorium and potassium, potassium silicofluoride, and aluminium at 1200°, and purified from free aluminium and silicon by treatment with potassium carbonate soln.	It forms quadratic plates resembling graphite in colour, has a sp. gr. 7·96 at 16°, and when heated combines readily with the halogens, oxygen, sulphur, selenium, or hydrogen chloride, but is not attacked by hydrogen at a red heat.	It is soluble in aq. soln. of the mineral acids, is not attacked by soln. of the alkali hydroxides, but is decomposed on fusion with sodium or potassium hydroxides.	For analysis, the compound was dissolved in aqua regia or in a mixture of hydrofluoric and nitric acids, or decomposed by fusing with moist sodium hydroxide.

The uses of thorium.—In addition to the use of thoria in the preparation of incandescent mantles described in the next section, small pastilles of mixtures of thoria with a trace of ceria have been used for searchlights, headlights of motor cars, etc.	The principal is that of the lime-light or zirconia light.	Certain preparations of thorium have been recommended as constituents of magnesium flash-light powders—e.g. thorium chromate, tungstate, etc.[7]—the thoriferous flash-light powders are said to evolve less smoke than if magnesium is used alone.	The use of thoria as a contact catalyst is indicated below.	R. Escales [8] described the use of thorium alloys as reducing agents.	E. W. von Siemens and J. G. Halske recommended an alloy of tungsten and thorium in the manufacture of the filaments for incandescent lamps.	W. Nernst used a mixture of zirconia, thoria, yttria, and sometimes a little ceria as a heating filament for his lamp.	C. Kästle, and F. W. S. Valentiner and R. Schwarz used thoria as a screen for X-rays.

Reactions of analytical interest.—The reactions with a soln. of thorium sulphate may be taken to typify the characteristics of those of thorium salts in general. A soln. of **ammonia** or of an **alkali hydroxide** produces a white precipitate of thorium hydroxide, insoluble in excess, but readily soluble in dil. acids.	A similar

precipitate is produced by **ammonium sulphide.** When thorium hydroxide is ignited it forms thorium oxide which is soluble in conc. sulphuric acid, only after a prolonged digestion. White thorium carbonate is precipitated by **ammonium carbonate** or **alkali carbonate.** The precipitate is soluble in an excess of the reagent, and when the soln. is heated it becomes turbid owing to the separation of a basic carbonate ; the soln. clears again on cooling. Ammonia causes no precipitation in the soln. Thorium salts are completely precipitated by **barium carbonate** in the cold. With **potassium sulphate,** the double salt $K_4Th(SO_4)_4.2H_2O$ is precipitated ; the double salt is sparingly soluble in water, and virtually insoluble in a conc. soln. of potassium sulphate. The corresponding sodium salt is readily soluble in water. All the thorium is precipitated from a boiling soln. by the addition of sodium thiosulphate. A white gelatinous precipitate is produced by hydrofluoric acid or by an alkali fluoride. A white precipitate is produced in feebly acid and neutral soln. by **potassium ferrocyanide ;** and feebly acid soln. also give a white precipitate when treated with **potassium azide,** KN_3. Nitric acid soln. of thorium salts give a white crystalline precipitate with **iodic acid.** Boiling soln. of thorium salts in hydrochloric acid give a flocculent precipitate when treated with **sodium hypophosphate.** Neutral soln., or soln. feebly acidified with sulphuric acid, give a white precipitate with **hydrogen peroxide,** and in soln. of ammonium carbonate, all the thorium is precipitated as hydroperoxide.

If the soln. of the thorium salt be not too acid, **oxalic acid** precipitates white crystalline thorium oxalate very sparingly soluble in oxalic acid and dil. mineral acids. A similar precipitate is produced by **ammonium oxalate ;** this dissolves when boiled with a large excess of the reagent. The soln. remains clear on cooling provided too much free sulphuric acid is not present, and a sufficient excess of ammonium oxalate is employed. The addition of hydrochloric acid to the boiling soln. of ammonium oxalate precipitates nearly all the thorium as oxalate. If ammonium acetate be present, no precipitate is produced by ammonium oxalate, but if hydrochloric acid be added to the soln., nearly all the thorium is precipitated as oxalate. A neutral, aq. soln. of a thorium salt gives a white precipitate with *m*-**nitrobenzoic acid ;** and with **aniline** *m*-**nitrobenzoate,** the precipitation is complete. All the thorium is precipitated from a soln. of a thorium salt in 40 per cent. alcohol by a soln. of **fumaric acid** in the same menstruum. These reactions are discussed more in detail in connection with the rare earths (**4.** 38, 5). Processes for estimating thorium have been devised which are based on the radioactivity.[9]

The individuality of thorium.—C. A. von Welsbach,[10] and B. Brauner have raised doubts about the individuality of thorium, and C. Baskerville claimed to have separated thorium into three elements—*neo-thorium,* at. wt. 220·6 ; *carolinium,* at. wt. 255·7 ; and *berzelium,* at. wt. 220·3—by precipitation as basic sulphite, or as citrate, followed by fractional sublimation of the chlorides. R. J. Meyer and A. Gumperz tried the fractional precipitation of thorium as chromate, and fractional sublimation of the chlorides, but G. Eberhard could detect no spectral difference in the fractions. B. Brauner fractionally hydrolyzed ammonium thorium oxalate into two series of fractions, *viz.* α-thorium with an at. wt. 233·5, and β-thorium with an at. wt. 232·5 ; and later, he stated :

The fact that α-thorium is inclined to form basic salts while β-thorium forms acid salts *beruht nur auf einem Zufall.* Apart from radioactive transformation products, thorium with an at. wt. 232·5 is an individual substance which is not admixed with any other quadrivalent element.

Hence, there is no sufficient reason for doubting the elementary nature of thorium. The evidence derived from the study of radioactivity, discussed in a later section, shows that thorium is slowly breaking down into radioactive degradation products and helium. F. Soddy estimated that 350 grms. of thorium nitrate furnished 2×10^{-10} grm. of helium in seven months.

The valency of thorium.—In 1828, J. J. Berzelius [11] ascribed the formula ThO

to thoria, the argument was based on the analogies which thoria bears to ceria, lanthana, didymia, and magnesia. In 1845, he said :

Since in potassium thorium sulphate the component bases are each associated with the equal quantity of sulphuric acid, there is some reason to assume, although it is by no means certain, that thoria contains one atom of the radicle and one atom of oxygen.

With increasing knowledge, the rare earth elements were found to be tervalent, while magnesium remained, like oxygen, bivalent. M. Delafontaine argued in favour of the quadrivalency of thorium from the isomorphism of thoria with stannic oxide, and titanic oxide ; and from the analogy between potassium thorium fluoride, and potassium zirconium fluoride. D. I. Mendeléeff showed if thorium be quadrivalent, its properties fit better into the periodic table than if its valency has some other value. P. T. Cleve also argued that thorium is quadrivalent in such compounds as thorium ferrocyanide, $ThFeCy_6$, analogous with K_4FeCy_6 ; the double salts of mercuric cyanide with thorium trihydroxythiocyanate, $nHgCy_2.Th(OH)_3SCy$; thorium formate, $(H.CO.O)_4Th.3H_2O$; a series of hydrated sulphates, $Th(SO_4)_2.nH_2O$; thorium pyrophosphate, ThP_2O_7 ; and sodium thorium carbonate, $3Na_2CO_3.Th(CO_3)_2$. He added that the thorium compounds are closely related with those of zirconium, but thorium does not furnish a monoxide like ZrO. L. F. Nilson compared a number of corresponding compounds of zirconium, tin(ic), and thorium—e.g. the chloroplatinates ; and L. Troost and L. Ouvrard showed that thorium is probably quadrivalent in the silicate $ThO_2.SiO_2$.

L. F. Nilson's value for the sp. ht. of the metal fits the sp. ht. rule only if thorium be quadrivalent. P. S. Baker, and B. D. Steele also showed that the quadrivalency of thorium is in harmony with the relationship of thorium to the other elements. G. Wyrouboff and co-workers assume that thorium is bivalent like the rare earth elements. He rejects any consideration based on the physical properties of the elements, and the periodic law ; and he arbitrarily gives an overwhelming weight to evidence based on his own observations on the isomorphism of the silicotungstates of calcium and the rare earth elements. This mode of conducting an inquiry has not gained many converts. The vap. density of thorium chloride at the b.p. of zinc determined by L. Troost fits the assumption that thorium is bivalent ; but determinations by G. Krüss and L. F. Nilson showed that at 1400°, thorium chloride dissociates, and if taken between 1050° and 1100°, the observations fit the assumption that the element is quadrivalent. On the other hand, W. Biltz suggested that at 1400° the mol. wt. corresponds with $ThCl_3$, and at lower temp. Th_2Cl_3. Against this, W. Biltz found that the mol. wt. of thorium acetylacetonate by the b.p. method, agrees with the formula $Th(CH_3.CO.CHCO.CH_3)_4$. Hence, it is concluded that thorium is quadrivalent.

The atomic weight of thorium.—Quite a large number of determinations have been made of the at. wt. of thorium. In 1829, J. J. Berzelius [12] analyzed thorium sulphate, and from his value for the ratio $ThO_2 : 2BaSO_4$, the at. wt. of thorium is between 236·0 and 240·1 ; from the analysis of the double potassium sulphate, his value for the ratio $ThO_2 : 2BaSO_4$ gives 240·7 ; and for the ratio $ThO_2 : 2K_2SO_4$, 236·9. In 1861, J. J. Chydenius computed 237·3 from the ratio $ThO_2 : 2SO_3$; 236·1 from $K_4Th(SO_4)_4.2H_2O : ThO_2$; 237·3 from $Th(CH_3.COO)_4 : ThO_2$; 241·2 from $Th(H.COO)_4 : ThO_2$; and 231·4 from $Th(C_2O_4)_2.2H_2O : ThO_2$. In 1863, M. Delafontaine gave 232·35 from the ratio $Th(SO_4)_2.9H_2O : H_2O$; and 234·7 from the ratio $Th(SO_4)_2.4\frac{1}{2}H_2O : ThO_2$. In the latter case, M. Delafontaine assumed the salt to be a tetrahydrate. In 1864, R. Hermann obtained 228·5 from the ratio $Th(SO_4)_2.4H_2O : H_2O$; and 231·7 from the ratio $ThO_2 : 2SO_3$. In 1874, P. T. Cleve obtained 234·03 from the ratio $ThO_2 : 2SO_3$; and 233·97 from the ratio $ThO_2 : 2CO_2$. In 1882, L. F. Nilson obtained 232·66 from the ratio $Th(SO_4)_2.9H_2O : ThO_2$ weighed in air, and 232·51 when the results are reduced for weighing in vacuo. He also obtained 232·16 and 232·61 from the ratio $ThO_2 : 2SO_3$, and 233·75 from $Th(SO_4)_2 : 9H_2O$. In 1887, G. Krüss and L. F. Nilson

obtained 232·61 from the ratio $ThO_2 : 2SO_3$ when weighed in air, and 232·49 when weighed in vacuo. In 1900, G. Urbain gave 233·79 from the ratio $ThO_2 : 2SO_3$; and 232·64 from the ratio $Th(SO_4)_2.8H_2O : ThO_2$. O. Hönigschmid and S. Horovitz obtained 232·15±0·016 from the ratio $ThBr_4 : 4Ag$; and 232·12±0·014 from the ratio $ThBr_4 : 4AgBr$. B. Brauner gave 232·21–232·39 from the ratio $ThO_2 : 2C_2O_3$; 232·34–232·52 from the ratio $ThO_2 : 2SO_3$; and 232·36 from the ratio $Th(SO_4)_2.9H_2O : ThO_2$. B. Brauner gave 232·49 for the best representative value, and F. W. Clarke, 232·6. The International Table for 1921 gives 232·4. The **atomic number** is 90. No **isotopes** have been reported by F. W. Aston. For the alleged **atomic degradation** of thorium to carbon, *vide* thorium nitrate. N. Yamada found that hydrogen is probably emitted by the bombardment of α-particles. F. Zambonini, and J. Beckenkamp investigated the atomic structure of thorium—*vide* hafnium.

§ 5. The Incandescent Mantle

In 1820, D. Brewster[1] suggested that the intense dazzling light which lime and other earths give in the blowpipe flame might be applied economically and usefully. He also showed that bits of wood, steeped in soln. of calcium or magnesium salts, after ignition, left the lime in a more attenuated state than ordinary lime, and gave a more intense light at a lower temp., and in 1835, W. H. F. Talbot showed that even the flame of a spirit-lamp sufficed to make lime incandescent provided the lime be in a very finely divided state such as obtained by incinerating blotting paper previously soaked in a soln. of a calcium salt. In 1826, T. Drummond showed that a cylinder of lime could be raised to incandescence by heating it in the flame of the oxy-hydrogen blowpipe, and he utilized the fact for producing an intense light, the so-called lime-light—*vide* hydrogen. The heat required to raise the cylinder of lime to the temp. of incandescence is considerable, because so much heat is dissipated by radiation and conduction. This is shown by heating coils of (i) thick, (ii) medium, and (iii) thin platinum wires in a Bunsen's flame ; the first becomes red hot, the second bright red, and the third may become incandescent and fuse. Buttons of zirconia and of magnesia heated by an oxy-coal gas flame were tried in Paris for street-lighting, but owing to the high cost, the project was soon abandoned. In 1848, J. P. Gillard tried heating a mantle of fine platinum gauze by the water-gas flame as a source of illumination. The results were good, but the surface of the metal was eroded by the flame gases, and the light-giving power deteriorated. In 1880, C. Clamond introduced lime and magnesia hoods, or mantles heated by coal gas flame fed with heated air. The hood was suspended in a net of fine platinum wire. Several modifications appeared—*e.g.* V. B. Lewis' incandescent burner, etc.

J. J. Berzelius in 1829, J. F. Bahr and R. Bunsen in 1866, and M. Delafontaine in 1874 showed that thoria, zirconia, yttria, erbia, and terbia emit *ein ausserordentlich blendendes Licht* at the temp. corresponding with that of a non-luminous gas flame. About 1880, C. A. von Welsbach[2] was attracted by the white or yellow incandescent light emitted by the rare earths when heated to a high temp. Erbia gave off a green light. In order to investigate the spectra of the incandescent earths, he soaked cotton with soln. of the earths, calcined the dried fabric, and obtained a coherent skeleton formed by the earth. The light emitted by lanthana was so bright that he tried a mantle of this earth as a source of illumination, but found that the mantle soon disintegrated to powder ; a mixture of lanthana and magnesia was more stable, but it became translucent and vitreous after 60–70 hrs.' use. He obtained better results with mixtures having zirconia as a base, but found that those containing thoria were best of all, but even here the results were not satisfactory. The thoria increased the emissive power of the associated earths, but it decreased very much after 50–60 hrs.' use. C. A. von Welsbach then found that the more he purified the thoria, the less the intensity of the emitted light. He thought that the process of purification resolved thorium into two substances, and that the luminous constituent accumulated in the mother-liquors. About 1890, he showed that the luminous constituent was cerium oxide. He found that a mixture of thoria with about 1 per cent. of cerium oxide has about three times

the emissive power of the older preparations. In 1892, this mixture—the so-called *Welsbach's mixture*—was adopted for the manufacture of mantles, and, in spite of numerous attempts, no improvement has been discovered. If, however, the press. be greater than that of the atm., a rather larger proportion of cerium oxide is needed.

The manufacture of incandescent mantles is described in monographs, etc., by L. C. Andes, C. R. Böhm, L. Castellani, H. W. Fischer, W. Gentsch, E. Glinzer, G. Hartwig, E. Hintz, G. Kern, G. von Knorre, V. Loos, M. M. Merle, H. von Oeschelhäuser, M. Rubnur, M. Söhren, etc. The flame is non-luminous like an ordinary Bunsen's burner ; and the mantle is hung so that it is heated by the burning gas. The mantle becomes incandescent. The mantles are made by saturating woven cotton, or artificial silk fabrics with a mixture of, say, thorium nitrate (48–49 per cent. ThO_2), 1000 grms. ; cerium nitrate, 10 grms. ; beryllium nitrate, 5 grms. ; magnesium nitrate, 1·5 grms. ; and water, 2000 grms. The object of the beryllium and magnesium nitrates is to strengthen the ash skeleton. The mantle is dipped in the soln. The fabric retains some of the salts in its pores. The impregnated mantle is then allowed to dry, and burnt off in a stove ; at the same time, the nitrates are transformed into oxides. The mantle is hardened and shaped in the blow-pipe flame and the result is a kind of fragile pottery which retains the form and shape of the original fabric. It would be too fragile for transit. It is therefore dipped in collodion and dried. The collodion is burnt off the first time the mantle is placed in position when it is no longer to be carried about. H. D. Griffith described the preparation of Nernst's filaments for laboratory work.

The incandescent or light-emitting power of the mantle is somewhat sensitive to variations in the composition of the mixture of earths. With the above-named mixture, the light has ten times the illuminating power of a flat flame burner using the same amount of gas. The photometry has been studied by H. Bunte, H. Drehschmidt, W. Wedding, etc. W. MacKean, and E. Glinzer have discussed the effect of various foreign matters on the light emissivity of the mantle. E. Baur said that the presence of gadolinia in the thoria is deleterious. O. N. Witt found that lanthana lessens the durability of the mantle ; didymia and yttria affect the luminosity and the refractoriness of the mantle ; and erbia imparts a greenish tinge to the light. H. E. Ives and co-workers tested the results obtained by replacing the ceric oxide with uranium oxide, manganese oxide, nickel oxide, lanthana, praseodymia, neodymia, and erbia.

The Welsbach mixture has a relatively high efficiency in translating heat into light. V. B. Lewes gives the following relative values for the light-emitting power of various oxides of commercial purity and of a high degree of purity :

	Pure.	Commercial.
Zirconia.	1·5	3·1
Thoria .	0·5	6·0
Cerium oxide .	0·4	0·9
Lanthana	—	6·0
Yttria .	—	3·2
Erbia .	0·6	1·7
Chromic oxide	0·4	0·4
Alumina	0·6	0·6
Baryta .	3·3	3·3
Strontia.	5·2	5·5
Magnesia	5·0	5·0

H. E. Ives and co-workers studied mantles made from the oxides indicated in Table IV, under like conditions. The whole group has a low light emissivity. The temp. of the flame was 2050°. Silica and beryllia have qualities almost complementary to those required for light production for their low temp. and the distribution of their emissive power with all the higher values in the infra-red, militate against a high luminous efficiency ; zirconia even at a low temp. has a relatively higher emissive power. In addition to light-emitting power, the further requirements are that the oxide employed must be (i) unaffected by atm. influences ; (ii) sufficiently refractory to retain its porosity, and not to melt or even vitrefy seriously at the temp. of the flame ; (iii) non-volatile ; and (iv) the shrinkage in

the burning and calcination of the nitrate-laden fabric must not be excessive. Hence, added E. St. John, the mantle is made from a fire-resisting material of small mass, small heat conductivity, large surface, and large light emissivity

TABLE IV.—LIGHT EMISSIVITY OF OXIDES.

Oxide.	Temp.	Rate of radiation.	Emissive power.	Radiant luminous efficiency.
Thoria . . .	1930°	1·10	0·044	0·000320
Zirconia . .	1670°	1·32	0·095	0·000143
Magnesia . .	1840°	1·10	0·053	—
Alumina . .	1725°	1·41	0·088	0·000390
Silica	1650°	1·71	0·130	—
Beryllia . .	1690°	1·61	0·110	—

when heated in the hottest part of Bunsen's flame. When tested by these criteria, it is found that thoria occupies a unique position as a basis for the mantle. It is readily shaped at the temp. of the blowpipe flame ; its thermal endurance in the oxy-coal gas flame is greater than that of any known oxide ; and in the conversion of the fabric soaked with thorium nitrate into the thoria skeleton, the shrinkage is smaller than is the case with any of the other substances. In converting thorium nitrate into thoria there is a large expansion—almost tenfold. Hence, the product is very porous or spongy.

While thorium oxide alone has a relatively small light emissivity, this quality is awakened by the addition of a trace of cerium oxide, and, as the proportion of the last-named oxide is gradually increased, the light emissivity of the mantle grows greater and greater, until, when the ratio CeO_2 : ThO_2 by weight is nearly 1 : 99, the maximum luminosity is attained, and any further addition of cerium dioxide reduces the emissivity until, when about 10 per cent. of cerium dioxide is present, the light emissivity is very small. These observations are illustrated by the measurements of G. P. Drossbach, and J. Lux. The latter found :

Per cent. of CeO_2 . . .	0	1	2	3	4	5 . . . 100
Illuminating power . .	3·3	143·3	120·5	105·6	91·0	82·9 4·0

A composite curve from the results of both observers is shown in Fig. 5. W. Muthmann and E. Baur believe that the thoria and cerium oxide form a solid soln. The powerful emissivity of the mixture could not have been foreseen from any known property of the constituent earths, and, added C. A. von Welsbach, "we can give no exact reason for the excitation of the emissive power of thoria by the cerium dioxide." Several hypotheses have been suggested to explain the increased luminosity : some consider the phenomenon to be a purely

FIG. 5.—Effect of Cerium Dioxide on the Light Emissivity of Thoria.

physical process due to temp. alone—e.g. W. Nernst, and H. le Chatelier and O. Boudouard, vide infra. Others attribute the phenomenon to catalytic action. F. Westphal suggested that the peculiar glow is a manifestation of energy due to the slow combination of acidic and basic oxides. H. E. Armstrong and T. M. Lowry, C. Killing, and R. Moschelles assumed that the particles of the cerium oxide are alternately oxidized and reduced by the rapid transition from one state to the other producing mol. oscillations—oscillatory oxidation—which cause a rise of temp. In the words of C. A. von Welsbach, who once advocated this hypothesis :

The gas of the flame successively and very rapidly oxidizes and reduces the emissive substance at the points where it is situated in the mantle. If the constituents of the mixture could form a compound when one of them is in a state of higher or lower oxidation, the compound would be quickly destroyed at the moment when the body concerned passes from the usual to the other degree of oxidation. The earths are in a state of extremely fine division, and are surrounded by a mantle of flame both oxidizing and reducing. If reduction takes place there is also decomposition, and if oxidation, there is recombination of these elements; these reactions may go on several million times a second, and mol. shocks are produced which give rise to luminous oscillations of the ether, and the body becomes incandescent.

This does not make it clear why the increased luminosity does not occur *pari passu* with an increase in the proportions of ceria. G. P. Drossbach, H. Bunte, R. J. Meyer and A. Anschütz, and V. B. Lewes ascribed the emissivity of Welsbach's mixture to some special action—catalytic action, or contact action—of the cerium dioxide in converting heat rays into light rays. Platinum foil continues to glow in a stream of coal gas after it has been heated to redness and the flame extinguished. It is assumed that a kind of surface combustion takes place. The metal is supposed to condense the coal gas and air on its surface, and render them so chemically active that they combine at a temp. below the ignition of the mixture, and the heat of the reaction suffices to keep the temp. of the foil at a red heat. H. Bunte showed that cerium oxide likewise lowers the temp. at which hydrogen and oxygen combine—from about 650° to 315·5°. This action is intensified by increasing the surface of the stimulant.

Spongy platinum, for example, without being previously heated may ignite the gas, and H. Bunte and H. Luggin have shown that the trace of finely divided cerium oxide, on the surface of the thoria, is so active that under suitable conditions the mantle can be kept luminous in a stream of coal gas and air :

A mica chimney is fixed over the mouth of a large Bunsen's burner so as to form a prolongation of the tube. The mixture of gas and air is ignited at the mouth of the chimney, and the air supply is regulated so as to give a non-luminous flame. An ordinary Welsbach's mantle is then hooked by its loop on to a platinum wire, and is held on the burning mixture of gas and air at the mouth of the chimney, until it glows and emits light in the usual way. On lowering the mantle through the flame into the mica chimney below, it continues to incandesce in the cold current of air and gas.

F. Haber and F. Richardt, however, state that the catalytic reactions on the mantle in Bunsen's flame have very little influence on its temp. The thoria, said A. Foix, serves as a carrier and dilution medium for the cerium oxide ; and, added C. Killing, the thoria is specially fitted for this purpose in virtue of its enormous surface (porosity) and its low sp. ht. F. Westphal, C. Killing, H. Bunte, and E. G. Love regarded the ceric oxide as a carrier of oxygen to the burning gas, but later, C. Killing gave up the hypothesis when he found that the mantle glowed with a greenish light in the chlorohydrogen flame ; H. E. Ives and co-workers also found that the efficiency of the mantle is but little if at all affected by the change from oxygen to chlorine.

A. A. C. Swinton found that Welsbach's mixture gave no more light than ordinary thoria when bombarded by the cathode rays ; and while purified thoria glowed brilliantly, purified ceric oxide gave scarcely any light. In the flame, on the contrary, the intensity of the glow with thoria and ceric oxide is nearly the same, although the colour is different. Observations on this subject were made by E. St. John, R. L. Swan, and R. J. Meyer and A. Anschütz. H. E. Ives and co-workers observed that the continued bombardment of the cathode rays imparted a bluish-grey colour to mixtures of thoria and ceric oxide, and the original colour was restored by heating the mantle in air. The cathode discharge thus acts as a reducing agent. The reducing condition increases the general emissive power of ceric oxide, and reduces the mantle temp. ; with thoria, as C. Fèry has shown, the reducing condition lowers the emissive power and augments the temp.

C. Féry concluded that a mantle of cerium oxide gives no light because the

radiation of heat is so great that the temp. cannot be raised sufficiently by the oxy-coal gas flame ; but when the cerium oxide is sufficiently attenuated by dilution with thoria, it can be raised to the required temp. E. St. C. Deville supported the view of C. Féry. In further support of this view, V. B. Lewes showed that under similar conditions :

Per cent. CeO_2 in thoria	0·1	1·0	10·0	100
Temp. of mantle 6 mm. above burner .	1610°	1570°	1355°	1125°
Temp. of flame in the same zone . .	1590°	1560°	1350°	1130°
Temp. of mantle 52 mm. above burner .	1468°	1441°	1209°	1020°
Temp. of flame in the same zone .	1430°	1439°	1234°	1032°
Illuminating power (candles per c. ft. of gas)	3·4	20·0	3·3	nil
Radiation value	140	152	218	234

Hence, added V. B. Lewes, thoria, owing to its low sp. ht., and low radiation power for heat, can be raised to the temp. of the flame while catalytic action on the still unburnt flame gases and air raises it a few degrees even above this point. Ceria when added in quantities up to 1·5 per cent. by weight, does not interfere with these conditions; but, by its still higher catalytic powers, it tends to focus the combustion of the extremely attenuated combustible constituents of the flame gases on the widely distributed ceria particles, and, by this localization, raise them to a far higher temp. than the mantle. This temp., however, cannot be detected by the thermocouple, which only gives the average temp. of the mass with which it is in contact, and fails to show the temp. of the 0·15 per cent. of ceria. The addition of more ceria to the mixture causes such a rapid cooling of both mantle and flame by radiation that the light at once begins to fall, and by the time 10 per cent. of ceria is in the mixture, the mantle gives us no more light than a thoria mantle, but a much increased heat radiation.

In 1898, H. le Chatelier and O. Boudouard claimed that the luminosity of mantles can be explained by the ordinary laws of selective radiation ; the subject was followed up by W. Nernst and E. Bose, who found that at equal temp. the radiation was nearly the same whether the mantle be heated by the gaseous products of combustion or electrically. Thus,

Wave-length . . .	6880	5890	5160	4770	4470
Flame heating . . .	0·770	1·000	1·36	2·39	4·21
Electric heating . .	0·790	0·987	1·37	2·34	4·09
Ratio	1·03	0·99	0·99	0·98	0·97

They conclude that since the substance of the mantle emits but little red light or ultra-red rays, and thus gives off but little energy in the form of heat, the mantle can, therefore, completely absorb the high temperature of the gas flame, and, in consequence, emit a relatively greater amount of light. H. Russell and A. F. Traver add that temp. alone cannot be the explanation because a slight change in the composition of the mantle should not cause so great a difference in the result— e.g. the luminosity of a mantle with 0·5 per cent. of cerium oxide is 13 times greater than a mantle of pure thoria even when the temp. is 100° less.

A. H. White and co-workers determined the temp. existing in mantles and in the flame. They found that with 0·342 sq. in. as unit area,

	Thoria mantle.	Welsbach's mantle.
Temp. inside mantle.	1600°	1600°
Temp. outside mantle	1510°	1410°
Heat conveyed to unit area of mantle (cals. per hr.) .	15790	15790
Heat conveyed from unit area of mantle (cals. per hr.) .	14380	13170
Heat transformed by unit area of mantle (cals. per hr.) .	1410	2620
Illumination per unit area (candles)	0·2	4·0

Otherwise, expressed, the difference in the energy transformed by the two mantles is 64×10^1 ergs per sec. per sq. cm., and the difference in the light emitted is 1·7 candle power per sq. cm. Taking the mechanical eq. of the light of a Hefner lamp to be $1·5 \times 10^5$ ergs per sec., then, if all the 64×10^5 ergs per sec. were

converted into visible light, the difference in the candle power would be 37·2 per sq. cm. The observed difference is therefore only 4·5 per cent. of the theoretical. According to H. E. Ives and co-workers, the total luminous efficiency of the mantle is 2·6 per cent. when heated by Bunsen's flame. In opposition to H. le Chatelier and O. Boudouard, and W. Nernst and E. Bose, A. H. White and co-workers found that the illumination is not solely a function of temp. because Welsbach's, at a temp. of 1410°, has a greater illuminating power than the thoria mantle at a temp. of 100° higher. They conclude that the exceptional efficiency of Welsbach's mixture is due to a solid soln. of cerium oxide in thoria, and that it has the power of transforming the heat of the flame into light more economically than other substances yet known.

G. C. Schmidt made spectro-photometric investigations on mixtures of thoria and cerium oxide, at various temp. He observed that the higher the temp., the bluer becomes the light yielded by the thoria. A similar result was obtained with mixtures of the two oxides all the time the ceria is below 0·5 per cent. of cerium oxide; when 0·5–1·5 of cerium oxide is present, the red rays and illuminating power increase; but beyond that percentage, the colour approaches that of cerium oxide, and the illuminating power decreases. Hence, added A. H. White and co-workers, the solid soln. of thoria and cerium oxide acts by so transforming the energy that more blue and green rays and less red rays are emitted by the glowing mantle than by the open flame. This means that more flame-energy is transformed into light and less into heat than is the case with the ordinary flame.

No reason is offered why 0·5–1·5 per cent. of cerium oxide and no other proportion has so marked an effect in exciting the light emissivity of the mantle. R. L. Swan found that the catalytic effect of mixtures of thoria and ceria on electrolytic gas is greatest when about 1 per cent. of ceria is present. It is suggested that the ceria acts by increasing the electron emission of the thoria, causing a greater ionization of the gases and a more efficient combination. W. Muthmann and E. Baur have suggested that thoria can form a solid soln. with up to about 1 per cent. of cerium dioxide, but if higher proportions be present, the excess acts as a foreign element diminishing the light emissivity of the mantle. R. J. Meyer and A. Anschütz, however, said that the thoria is sat. only when about 7 per cent. of ceric oxide is present, but they have not decided whether this is a solubility equilibrium, or whether a chemical compound, $9ThO_2.CeO_2$, is formed. Hence, it is not probable that the homogeneity of the solid soln. is an essential condition for the special light emissivity characteristic of the mantle; but, if part of the solid soln. is dissociated, it is possible that the maximum emissivity occurs with that concentration for which the soln. is completely dissociated. This hypothesis corresponds with that suggested by E. Goldstein, and P. Wäntig for the luminescence of certain substances exposed to the cathode rays. E. St. John could detect scarcely any signs of phosphorescence or fluorescence by the mantle.

Various forms of the physical theory of the *auer*, or *Welsbach's mantle*, or the *incandescent mantle* have been discussed by W. Gentsch, E. St. John, W. Krebs, C. Hohmann, O. Lummer and E. Pringsheim, H. Thiele, E. Baur, F. Bössner, J. Swinburne, J. Hofmann, C. E. Guillaume, E. Podszus, etc. A physical theory has been developed by H. Rubens and co-workers. He showed that owing to the low emissive power of a thoria mantle, it attains a comparatively high temp., while a mantle of ceric oxide has a comparatively low temp. owing to its high emissivity. This is illustrated by H. E. Ives and co-workers' observations, Fig. 6, on the relation between the temp. for maximum luminosity and radiation on mantles with different proportions of thoria and ceric oxide. Ceric oxide has a sharp absorption (emission) band in the visible spectrum, and the radiation of energy is so great that the temp. of a cerium oxide mantle is kept comparatively low. Starting then
Fig. 6.—Relation between Composition and Temperature of Mantle.

with thoria, and introducing cerium oxide, the emission band broadens, and the total radiation increases, while the temp. is lowered. The maximum luminous efficiency is attained when the rise in the visible emission is balanced by the fall in temp. due to the increased radiation. R. L. Swan discussed this action. R. W. Wood, and H. E. Ives and co-workers gave a hydraulic analogy for the behaviour of the burner and mantle.

Imagine the mantle to be represented by a vertical cylindrical tank into which water is flowing at a constant rate from a tap (Fig. 7). Let the wall of the tank be perforated by holes of various sizes. The water which squirts out through these holes is the radiation, and the various sizes of holes represent various wave-lengths. If the smaller holes are more numerous at the top of the tank, then the higher the water rises the more will squirt out through the smaller holes, thus occupying the behaviour of a material radiator, water *height* being taken to represent *temperature*. If the tank contains many holes, the water will not rise very high, and, conversely, in one with only very few holes the water will rise higher, thus copying the behaviour of mantles of high and low emissive powers, in so far as their temp. characteristics are concerned. If the holes are all made small, only squirts of small size will be present, and the water will rise higher than if the holes of all sizes are present, thus copying the characteristics of a selective radiator like the mantle. In order for this tank to represent the behaviour of the mantle with respect to the amount of radiation, it is only necessary to imagine a vertical seam of the tank to have been left unsoldered, so that a bad leak is present, to represent the convection and conduction losses. The higher the water rises, as when the radiating holes are made in number, the more is lost through the leaky seam, and so the less is "radiated" through the holes. Obviously, with a constant rate of supply the advantage of increased "temperature" is being more and more offset by the leakage.

§ 6. Thorium Oxides and Hydroxides

According to J. R. Rydberg,[1] thorium furnishes only one oxide—*viz.* **thorium dioxide**, ThO_2, or **thoria**. J. Locke reported *thorium pentatritaoxide*, Th_3O_5, but H. P. Stevens regards this as one of the condensed or polymerized oxides classed as one of *meta-oxides* of G. Wyrouboff. According to G. Krüss, *thorium monoxide*, ThO, is not formed when thorium oxysulphide, $ThOS$, is heated to a red or white heat in a stream of hydrogen. G. P. Drossbach, and W. Bruno obtained what has been called *thorium peroxide*, Th_2O_7. There are also thorium hydroxide, $Th(OH)_4$, and a number of colloidal forms, as well as hydrated peroxides.

Thorium dioxide occurs associated with uranium dioxide as the mineral thorianite (*q.v.*). The amorphous oxide is obtained by heating the metal in air or in oxygen, or by oxidizing the metal with molten potassium chlorate. It is also produced when the hydroxide or various salts with the volatile oxyacids are calcined. J. F. Bahr,[2] and A. E. Nordenskjöld and J. J. Chydenius made crystals of the dioxide by heating the amorphous oxide with borax in a pottery oven ; L. Troost and L. Ouvrard, by heating the dioxide with molten potassium orthophosphate ; and A. Duboin, by melting thorium fluoride with sodium carbonate, or by melting a mixture of thorium dioxide, sodium fluoride, and sodium carbonate.

The amorphous oxide is a snow-white powder. O. Hahn studied the surface area of the particles of precipitated thoria in terms of adsorbed radioactive matter. The **crystals** obtained by the borax fusion were stated by A. E. Nordenskjöld to be tetragonal, and isomorphous with rutile and cassiterite ; while those obtained by the phosphate fusion were stated by L. Troost and L. Ouvrard to be octahedra belonging to the cubic system. A. Duboin said that the crystals he obtained were similar to those of thorium fluoride. G. Wyrouboff said that the crystals of thoria are isomorphous with those of cerium dioxide, and those of calcium or strontium monoxide. V. M. Goldschmidt and L. Thomassen, M. L. Huggins, A. E. van Arkel, and W. P. Davey studied the **X-radiogram** of thoria. The side of the elementary cube is $5·61 \times 10^{-8}$ cm., and there are 4 mols. per cube. G. R. Levi found that the precipitated hydroxide dried at temp. up to 340° is amorphous ; but the oxide obtained by heating the hydroxide to 1050°, or the nitrate or oxalate to 750°, is crystalline with the same X-radiogram in all cases. J. J. Berzelius gave 9·402 for the **specific gravity** of the crystals ; A. Damour, 9·366 ; J. J. Chydenius, 9·228 ; J. F. Bahr, 9·77 ; A. E. Nordenskjöld, 9·21 ; C. Baskerville, 9·188–9·380 at 4° ; L. F. Nilson, 10·220 at 17° ; L. Troost and L. Ouvrard, 9·876 at 15° ; and B. Brauner, 9·690 at 20°/4°. According to L. F. Nilson and O. Pettersson, the deviations in the value of this constant are due to entrained air or moisture, and to the presence of impurities in the oxide. G. von Hevesy studied the mol. vol. of the oxides of this family of elements. L. F. Nilson and O. Pettersson gave 0·0548 for the **specific heat** of the oxide between 0° and 100°. The mol. ht. runs parallel with those of zirconium ; cerium ; titanium, tin, and manganese dioxides. G. B. Pegram and H. Webb found that owing to its radioactivity, a gram of thoria develops $9·60 \times 10^{-6}$ cal. per hour—*vide* the radioactivity of thorium.

E. Tiede and E. Birnbrauer said that the **melting point** approximates to 2000°, and the oxide at the same time volatilizes. O. Ruff and co-workers gave 2440° for the m.p. H. C. Greenwood observed no signs of the dissociation of thoria at high temp. F. Born estimated thoria to be dissociated into metal and oxygen to the extent of 10^{-27} at 2000°, and 6×10^{-6} at 3000°. W. R. Mott gave 4400° for the **boiling point** of thoria. H. von Wartenberg gave for the **heat of formation** from thorium, 326·0 Cals. with an error of $\pm 0·5$ per cent. C. A. Matignon said that the heat developed by the union is 42·8 Cals. per gram-atom of oxygen.

When purified thoria is strongly heated, it emits a pale blue light of feeble **illuminating power,** but if the thoria be mixed with one per cent. of cerium oxide, a brilliant light is emitted. Such a mixture is used in making the well-known incandescent mantles—*vide supra.* C. Féry found that in an oxidizing flame, the colour of the emitted light has a rose tint, and in the reducing flame, at the same temp., the light has a greenish tint. B. Monasch employed a thoria preparation as cathode in an arc-lamp. W. E. Forsythe measured the emissivity of thorium oxide for $\lambda = 0·665\mu$, and found 0·15 at 1800° K., and 0·4 at 1400° K. K. Teucke examined the radiation emitted when thoria is bombarded by cathode rays. W. W. Coblentz found the **ultra-red emission spectrum** has no marked emission bands, and the whole spectrum is suppressed up to 7μ; after which, as found by H. Rubens, the emissivity approaches that of a complete radiator. H. Schmidt-Reps studied the ultra-red emissivity of thoria. The **reflecting power** of thorium oxide, for light of wave-length $0·60\mu$, was found by W. W. Coblentz to be 86·1 per cent.; for light of wave-length $\lambda = 4·4\mu$, 46·9 per cent.; for $\lambda = 8·8\mu$, 7·11 per cent.; and for $\lambda = 24\mu$, 10 per cent. N. Ahmad measured the absorption of γ-rays by thoria. E. L. Nichols and D. T. Wilber, and W. Crookes found that when thoria is exposed to the **cathode rays,** it exhibits a feeble phosphorescence, so also in **ultra-violet light.** Thoriferous minerals, according to C. Baskerville, do not exhibit fluorescence or phosphorescence. A. Karl observed that thoria shows **triboluminescence.** E. L. Nichols and H. L. Howes found there is not a luminescent spectrum with the incandescent oxide. O. Hahn studied the emanating powers of thorium oxide and hydroxide prepared in different ways; and H. J. Spanner, the thermionic emission of electrically charged particles. L. F. Nilson and O. Pettersson, and K. A. Angström found that thorium dioxide is diamagnetic; and W. Gerlach studied the behaviour of thorium in a magnetic field.

According to W. Crookes,[3] thoria is hygroscopic and absorbs **gases** with some avidity; W. Biltz found that it is difficult to obtain a constant weight by calcination owing to the absorption of **moisture.** R. J. Meyer and A. Gumperz found that when calcined at a high temp. the oxide is less sensitive than when calcined at a lower temp. According to H. E. Ives and co-workers, when white thoria is calcined in a quartz tube heated by Bunsen's flame, no change in colour is perceptible. According to R. J. Meyer and A. Anschütz, if a mixed soln. of thorium and cerium nitrates be evaporated to dryness and ignited about 7 per cent. of the ceric oxide forms a solid soln. with the thoria. E. Newbery and J. N. Pring found that the dioxide is not reduced by **hydrogen** at 2000° and 150 atm. press. H. von Wartenberg and co-workers discussed the reduction of thoria by hydrogen under press., and found that it can be reduced by hydrogen in the presence of another metal—*e.g.* tungsten. At 1250°, tungsten dissolved 0·07 per cent. thorium, and at 2000°, 0·24 per cent. J. J. Berzelius, and J. J. Chydenius found that strongly ignited thoria does not dissolve in **nitric or hydrochloric acid,** but N. J. Berlin, and G. Wyrouboff and A. Verneuil found that if the oxide, prepared by heating to redness the oxalate, nitrate, chloride, or hydroxide, be repeatedly evaporated with small quantities of these acids, a mass is formed which dissolves in water, forming an opalescent soln. resembling the so-called meta-oxides of zirconium and tin (ic). V. J. Spitzin found the solubility of thoria expressed in mgrm. ThO_2 per litre at 25° to be : N-H_2SO_4, 2·0 ; N-HNO_3, 0·6 ; N-HCl, 0·5 ; $0·8N$-$C_4H_6O_4$, 0·3 ; N-NaOH, less than 0·05 ; N-Na_2CO_3, less than 0·03 ; N-K_2CO_3, less than 0·02 ; and in water, less than 0·02. The solubility

of thoria in salt soln. is small, but greater in sulphates than in chlorides. According to J. J. Berzelius, and J. J. Chydenius, when thoria is heated with **sulphuric acid,** it is slowly converted into the sulphate; T. Sollmann and E. D. Brown made some observations on the solubility of thoria in this acid; and they found that when thoria is fused with **sodium hydrosulphate,** the mass obtained is soluble in water. T. Hiortdahl found that no carbon dioxide is evolved when thoria is fused with **sodium carbonate;** and J. J. Berzelius said that thoria does not become soluble in hydrochloric or nitric acid after it has been fused with **alkali hydroxides.** C. J. Smithells found that thoria is reduced to thorium by metallic **tungsten.**

J. J. Berzelius was not able to obtain the metal by the action of **carbon** or **potassium** on thoria, and H. C. Greenwood found that at 1600° in an evacuated atm., thorium carbide is formed. B. du Jassonneix obtained thorium boride by heating thoria with **boron** in an electric furnace; and O. Hönigschmid, thorium silicide by heating thoria with **silicon.** When heated in **carbon tetrachloride,** a mixture of chlorine and **sulphur chloride,** a mixture of carbon monoxide and chlorine, **carbonyl chloride,** or **phosphorus pentachloride,** thorium chloride is formed—*vide* the chloride.

Ignited thoria has been used as a **catalytic agent** in many reactions. H. B. Baker found that it ionizes many gases, and accelerates the reaction between nitric oxide and moderately dried hydrogen; but with thoroughly dried hydrogen there is no measurable change with 5 mins.' heating at 530°. L. and P. Wöhler and W. Plüddemann observed that it accelerates the oxidation of sulphur dioxide by oxygen. P. Sabatier and A. Mailhe observed that if an alcohol be passed over thoria at 300°–350°, the alcohol is decomposed in the same way that it would be by sulphuric acid to form olefines and water; but if the temp. be kept low, an ether is formed; A. Mailhe found that the vap. of esters are decomposed by heated thoria, forming ethers, olefines, primary alcohols, and carbon dioxide; and he found that when a mixture of ammonia and alcohol vap. is passed over thoria at 380°, the main product is a primary amine, but some secondary and tertiary amines are also formed. J. B. Senderens, and R. H. Pickard and J. Kenyon obtained good yields of ketones by passing a mixture of the vap. of two organic acids over heated thoria. S. Medsforth examined the effect of thoria on nickel as a catalyst in the reduction of carbon monoxide and dioxide by hydrogen. J. Aloy and C. Rabaut found that the presence of thoria inhibits the saponification of benzoylated cyanhydrins by acetic acid. G. R. Levi, S. Komatsu and B. Masumoto, E. Sabatier and A. Mailhe, and J. N. Pearce and A. M. Alvarado studied the catalytic action of thoria on ethyl acetate, and on the dehydration of alcohol; and W. W. Russell and H. S. Taylor, on the hydrogenation of carbon dioxide.

According to J. J. Berzelius,[4] and P. T. Cleve, **thorium hydroxide,** $Th(OH)_4$, or $ThO_2.2H_2O$, is precipitated quantitatively from a soln. of thorium sulphate when alkali hydroxide or ammonia is added. The gelatinous precipitate is well washed, and when dried over sulphuric acid, it furnishes a white powder. When alkali hydroxide is employed, the precipitant is retained very tenaciously, and T. Sollmann and E. D. Brown found that nine times washing by a centrifuge are needed to furnish a liquid neutral to litmus. G. Krüss and W. Palmaer preferred to agitate solid thorium sulphate with warm aq. ammonia, and boil the resulting powder with dil. ammonia. The product was washed with water free from sulphates. Several other precipitating agents give the hydroxide—*e.g.* C. Baskerville, and H. Erdmann used sodium nitrite; P. Jannasch and J. Schilling, hydroxylamine; and L. M. Dennis and F. L. Kortright, potassium azide. F. J. Metzger boiled thorium thiosulphate or oxalate with potassium hydroxide. O. Angelucci noticed that thorium hydroxide is precipitated on the anode when a soln. of thorium nitrate is electrolyzed. H. T. S. Britton studied the electometric precipitation of the hydroxide. Sodium acetate yields a precipitate with thorium sulphate soln. when the acidity has attained the value $p_H=3\cdot4$ obtained by adding 10 c.c. of sodium acetate soln., and with 25 c.c. the precipitation was a maximum, while with 30 c.c. of soln. the precipitate—chiefly basic sulphate—

dissolved. No precipitation occurred with thorium chloride soln., though F. Haler obtained one by boiling a soln. of the chloride with sodium acetate. With sodium tartrate, precipitation from soln. of thorium chloride began when the acidity had attained the value $p_H = 1.75$. The precipitate consisted of basic tartrate.

P. T. Cleve's analysis of the product dried at 100° corresponds very nearly with $ThO_2.2H_2O$. As J. J. Berzelius, and G. Krüss and W. Palmaer have emphasized, the hydroxide readily absorbs carbon dioxide from the air; and accordingly in some cases, the analyzed hydroxides have been contaminated with some carbonate. G. Wyrouboff and A. Verneuil treated a soln. of thorium chloride with aq. ammonia; the washed product was dried over potassium hydroxide until the weight was constant. All the operations were conducted in the cold. The composition corresponded with $ThO_2.5H_2O$, or the *trihydrate*, $Th(OH)_4.3H_2O$; if dried at 130°, 8·8 per cent. of water was lost, and the product approximated $ThO_2.2·8H_2O$, say the *monohydrate* $Th(OH)_4.H_2O$. The hydroxide loses all its water when calcined at a white-heat. T. Sollmann and E. D. Brown said that the hydroxide is insoluble in water, but prolonged washing with water may peptize the hydroxide. H. A. McTaggart found that a small conc. of colloidal thorium hydroxide suspended in water imparts a positive electric charge to a sphere of immersed air (with water alone, the charge is always negative). There is a reversal in the sign of the charge as the size of the bubble of air decreases. According to P. T. Cleve, the hydroxide is not soluble in soln. of the alkali hydroxides, or in an aq. soln. of ammonia. The moist hydroxide, said J. J. Berzelius, dissolves quickly in acids, but the dried hydroxide dissolves rather slowly. According to T. Sollmann and E. D. Brown, the hydroxide dissolves quickly in conc. hydrochloric acid, and slowly in the dil. acid; the speed of dissolution is increased by raising the temp., but decreased if the washing of the hydroxide has been prolonged, or if the hydroxide has been allowed to stand for some time; but if the precipitated hydroxide be boiled in water or if it has stood for 15 hrs. at 100°, the solubility is not diminished. L. Pissarjewsky gave 29·893 Cals. for the heat of soln. of moist thorium hydroxide in nitric acid. P. T. Cleve found the moist hydroxide dissolves in bromine-water; and J. F. Bahr showed that if chlorine be passed through water in which the hydroxide is suspended, part of the latter is dissolved; and the undissolved portion dissolves in water. H. Grossmann noted that a little thorium hydroxide dissolves in sulphurous acid, and is re-precipitated on boiling the soln. Thorium hydroxide was found by T. Sollmann and E. D. Brown to be less soluble in citric acid and in tartaric acid than it is in hydrochloric acid; and to be soluble in a soln. of sodium chloride, sodium citrate, potassium sodium tartrate or ammonium oxalate. J. J. Chydenius said that it is insoluble in oxalic acid, molybdic acid, or hydrofluoric acid, but is transformed by these acids into the corresponding salts. According to K. C. Sen and N. R. Dhar, thorium hydroxide is not precipitated by alkali hydroxide from soln. of thorium salts in the presence of sugars, dextrin, starch, or glycerol, presumably owing to the peptization of the hydroxide. N. G. Chatterji and N. R. Dhar also investigated this subject. J. Böhm and H. Niclassen studied the crystallization of the amorphous hydroxide.

N. J. Berlin [5] reported that thorium dioxide, prepared by the gentle ignition of the oxalate or hydroxide, behaves in a peculiar way towards hydrochloric acid for, if repeatedly evaporated with a small quantity of hydrochloric or nitric acid, the syrupy liquid which is formed dissolves in water to form an opalescent soln. which may be coagulated by acids or salts. J. F. Bahr, and P. T. Cleve made thorium dioxide possessing these qualities by calcining the oxalate; H. P. Stevens, by calcining the nitrate; G. Wyrouboff and A. Verneuil, by calcining the hydroxide; and J. Locke, by heating thorium dioxide in a stream of hydrogen. J. Locke regarded the product as **thorium meta-oxide,** Th_3O_5, but H. P. Stevens, showed that the oxide has the same composition as ordinary thoria, $(ThO_2)_n$; and G. R. Levi, that the X-ray examination disproves the assumption that the meta-oxide is a distinct variety. G. Wyrouboff and A. Verneuil regarded the

products as well-defined meta-oxides and not mixtures ; and regarded them as *condensed oxides* of different degrees of polymerization ; the condensation is necessarily accompanied by a change in the valency of the oxide.   J. Locke's analysis showed the presence of water, but G. Wyrouboff and A. Verneuil, and H. P. Stevens showed that the water was derived from the incompletely dried gas, for the product is very hygroscopic.   H. P. Stevens found that the weight of a gram of the oxide increased 2 per cent. when allowed to stand in the balance case for 5 mins.   J. Locke gave 8·733 for the sp. gr. at 15°.   G. Wyrouboff and A. Verneuil showed that the less condensed oxide, or rather the oxide which has been calcined at a relatively low temp., dissolves completely in hydrochloric acid or nitric acid when the mixture is heated to 120° in a sealed tube.   The normal chloride or nitrate is formed ; and they added that if the calcination be carried too far, *i.e.* if the oxide be condensed too much, it loses the faculty of uniting with the acids.   When the meta-oxide is heated with not too dil. sulphuric acid, the normal sulphate is formed. E. Chauvenet prepared soluble addition compounds with a number of acids.   If one of these salts—*e.g.* thorium meta-oxychloride—be treated with aq. ammonia, **thorium metahydroxide** is produced.   It resembles ordinary thorium hydroxide in appearance.   Its composition $ThO_2 : H_2O$ is indefinite—presumably on account of its colloidal nature.   H. P. Stevens compared it with metastannic acid, and called it *metathoric acid ;* and he also called ordinary thorium hydroxide, *thoric acid.*   He said that unlike normal thorium hydroxide, thorium metahydroxide does not absorb carbon dioxide from the air, and is less basic.   It is gradually converted into thorium hydroxide when allowed to remain in contact with water, and it dissolves in mineral acids if an excess of acid is carefully avoided.   When prepared from a meta-oxychloride rich in chlorine, it requires more acid for dissolution than when prepared from a compound poor in chlorine, and a soln. of meta-oxychloride requires more acid to precipitate it as the percentage of chlorine increases.

The least polymerized form of the meta-hydroxide was stated by G. Wyrouboff and A. Verneuil to be somewhat impure ; it is not stable, and begins to polymerize at 110° with the elimination of water, and approximates closer and closer to $6ThO_2.H_2O$.   It is insoluble in hydrochloric or nitric acid, but forms compounds with these acids with the evolution of much heat.   The products are then said to be soluble in water.   If these compounds are dried, and treated with ammonia, they lose the acid radicle, and form a horn-like mass.   According to G. Wyrouboff and A. Verneuil, the hydroxide, $6ThO_2.H_4O$, is precipitated by treating the more condensed form of the meta-oxychloride or meta-oxynitrate with ammonia.   They gave the formula $12ThO.H_2O$ in accord with their view that thorium is bivalent.   P. T. Cleve obtained $4ThO_2.H_2O$ by treating a colloidal soln. of thorium hydroxide with ammonia.   J. Locke obtained $3ThO_2.2H_2O$, which he represented as $Th_3O_5.2H_2O$, by evaporating the meta-oxide to dryness with hydrochloric acid, dissolving the residue in hot water, and treating it with ammonia.   When dried at 100°, it loses a mol. of water and furnishes $3ThO_2.H_2O$, which is also obtained by treating the meta-oxide with hydrochloric acid.   G. Wyrouboff and A. Verneuil also reported $2ThO_2.H_2O$; and $8ThO_2.9H_2O$.   The latter was produced by treating $Th_{16}O_7(OH)_{16}Cl_2.2HCl$, solid or soln., with ammonia and drying to constant weight over potassium hydroxide.

Opalescent liquids were obtained by J. F. Bahr, P. T. Cleve, G. Wyrouboff and A. Verneuil, etc., by evaporating to dryness a mixture of hydrochloric or nitric acid and thorium meta-oxide and taking up the mass with water.   The sol. is **colloidal thorium oxide or hydroxide.**   It is not flocculated by heat, but is coagulated by acids and many other salts ; and the colloid is peptized when the salts are removed by water.   W. Biltz and co-workers [6] dialyzed dil. aq. soln. of thorium nitrate, which on evaporation yielded a gum-like mass insoluble in water.   The hydrosol has a positive charge, and when the suspension in water is electrolyzed, it migrates to the cathode.   O. Hauser and F. Wirth obtained a flocculent hydrogel by boiling a very dil. aq. soln. of thorium sulphate.   A. Müller prepared a conc. hydrosol of thorium hydroxide by thoroughly washing the hydrogel from 20 grms. of thorium nitrate, and boiling it with water containing 10 grms. of the nitrate per 50 c.c.   Colloidal forms were also described by E. Stiasny, I. Kreidl and G. Heller, and J. Duclaux.   B. Szilard prepared colloidal thorium hydroxide, free from electrolytes,

by decomposing thorium nitrate with excess of dil. ammonia and washing the residue until free from ammonia, which takes three to six days. The product is a fine, milky suspension, in which the particles cannot be separated either by filtration or decantation; it is precipitated by electrolytes and by the carbon dioxide of the air. He also made colloidal thorium hydroxide, containing a little electrolyte, by adding precipitated thorium hydroxide to thorium tetrachloride so long as the former is dissolved. This soln. is much more stable than that free from electrolytes, is not affected by light or by boiling, and is not precipitated by small quantities of electrolytes or by weak acids. K. C. Sen and N. R. Dhar studied the peptization of colloidal thorium hydroxide by soln. of sugars, starch, glycerol, and dextrin. According to F. Haber, the hydrogel shows a feeble X-radiogram which is regarded as evidence of crystallinity. J. Böhm and H. Niclassen found that X-radiograms of the dried soln. were characteristic of amorphous substances, and that on ageing becomes crystalline. H. Rheinboldt and E. Wedekind studied the adsorption of dyes by the colloid.

L. de Boisbaudran,[7] P. T. Cleve, L. Pissarjewsky, and G. Wyrouboff and A. Verneuil obtained what was called **thorium peroxide** by treating a cold soln. of a thorium salt with ammonia and hydrogen dioxide. L. Pissarjewsky also obtained a similar product by treating thorium hydroxide with hydrogen peroxide; and W. Bruno, by treating a conc. soln. of a thorium salt at 60° with 30 per cent. hydrogen dioxide. According to L. Pissarjewsky, the white gelatinous precipitate is a hydrated thorium peroxide derived from the hypothetical **thorium hemiheptoxide,** Th_2O_7. It is assumed that hydrogen dioxide is a monobasic acid which reacts with thorium hydroxide, forming **thorium tetrahydroperoxide,** $Th(O_2H)_4$; and that this compound hydrolyzes in stages furnishing **thorium dihydroperoxide,** $Th(O_2H)_2(OH)_2$, and **thorium monohydroperoxide,** $Th(O_2H)(OH)_3$. The last-named product is considered to be a hydrated form of *thorium trioxide*, namely, $ThO_3.2H_2O$. G. Wyrouboff and A. Verneuil do not agree with L. Pissarjewsky's interpretation of these reactions, and believe that a complex mol. is formed containing peroxidized oxygen, hydroxyl radicles, and an acid residue. Thorium tetrahydroperoxide is very unstable, and slowly loses oxygen, passing into the hydrated trioxide, which is much more stable. When heated, it loses oxygen. When the hydrated hemiheptoxide is kept under water free from carbon dioxide, or on a porous tile over sulphuric acid, and soda-lime, it gradually reverts to thorium dioxide. The heat of neutralization $Th(OH)_4 + H_2O_2$ is 8·810 Cals.; the heat of soln. of $\frac{1}{2}Th_2O_7$ in dil. nitric acid is 17·184 Cals. When treated with dil. sulphuric acid, hydrogen dioxide is formed, and with conc. sulphuric acid, ozonized oxygen is evolved. The precipitate obtained by the action of hydrogen dioxide and ammonia is a mixture of the different products of the hydrolysis of the hemiheptoxide. L. Pissarjewsky also made the monohydroperoxide by the action of soln. of sodium hypochlorite on thorium hydroxide; by the action of chlorine on a suspension of thorium hydroxide in $2N$-sodium hydroxide; and by the anodic oxidation of a suspension of thorium hydroxide in an alkaline soln. of sodium chloride. L. Pissarjewsky found that the monohydroperoxide behaves towards dil. and conc. sulphuric acid like the tetrahydroperoxide, and he gives for the heat of formation of $ThO_2.nH_2O + O = ThO_3.nH_2O$ $-14·290$ Cals. The monohydroperoxide showed no signs of decomposition after keeping 24 hrs. According to G. P. Drossbach, when a thorium salt soln. is treated with anodic oxygen; or with hydrogen dioxide; or shaken with air, and the soln. evaporated, the product contains more oxygen than corresponds with thorium dioxide. If heated, or treated with strong acids, the excess oxygen is given off by the peroxidized salt.

§ 7. Thorium Fluorides

According to J. J. Berzelius,[1] when thorium hydroxide is treated with an excess of hydrofluoric acid, a heavy, insoluble, white powder is formed, **tetrahydrated thorium fluoride,** $ThF_4.4H_2O$. J. J. Chydenius obtained the same product as a gelatinous precipitate by adding hydrofluoric acid to a soln. of thorium chloride ; when dried in air, the composition corresponds with $ThF_4.8H_2O$, but four mols. of water are lost when dried in vacuo. E. Chauvenet made the same compound by decomposing thorium nitrate with silver fluoride, and drying the product in vacuo over sulphuric acid until the weight was constant. According to J. J. Chydenius, the hydrate loses up to 6·94 per cent. of water at 100° ; 8·26 per cent. at 140°. The loss of two mols. of water from a mol. of the salt represents 9·42 per cent. loss. The salt is partially hydrolyzed during the calcination, but J. J. Berzelius said that the fluoride is not completely decomposed by ignition, or by heating it with potassium. A litre of water at 25° was found by V. I. Spitzin to dissolve 0·17 mgrm. of tetrahydrated thorium tetrafluoride.

H. Moissan and H. Martinsen found that fluorine displaces chlorine from the anhydrous chloride, or bromine from the anhydrous bromide, forming anhydrous **thorium fluoride,** ThF_4 ; E. Chauvenet obtained the same product by passing dried hydrogen fluoride over the heated chloride, or, better, the bromide. A. Duboin made anhydrous thorium fluoride by melting potassium thorium fluoride, $KThF_5$, with an excess of potassium chloride or bromide ; and also by melting in a crucible lined with potassium chloride or a mixture of sodium and potassium chloride, a mixture of a mol of anhydrous thorium sulphate and 4 mols of potassium or sodium fluoride. The crystals belong to the cubic system, elongated in the direction of one of the axes as in certain specimens of cuprite, they melt at a red heat, are not attacked by conc. sulphuric acid, are slowly decomposed by the dil. acid or by hydrochloric acid, and on fusion with sodium carbonate yield transparent crystals of thoria which closely resemble the crystals of the original fluoride.

When tetrahydrated thorium fluoride, or thorium fluosilicate, is heated to 800° in a platinum boat in a stream of dry hydrogen fluoride, E. Chauvenet found that it is converted into **thorium oxyfluoride,** $ThOF_2$, a white, insoluble, amorphous powder, which is decomposed by sulphuric acid. A. Duboin melted potassium thorium fluoride with a small excess of potassium chloride and gradually added thorium sulphate. The cold mass was digested with water, and cubic crystals of an oxyfluoride of indefinite composition remained.

According to M. Delafontaine, thorium fluoride forms double fluorides analogous with those of zirconium. Neither J. J. Chydenius, nor A. Rosenheim and co-workers succeeded in preparing *ammonium thorium fluoride* or *sodium thorium fluoride* by processes analogous to those employed for preparing the double potassium salt. According to A. Rosenheim, **potassium dithorium enneafluoride,** $KTh_2F_9.6H_2O$,

is formed by precipitation with potassium hydrofluoride from a soln. of a thorium salt as a gelatinous precipitate which soon becomes pulverulent when allowed to stand in contact with the mother-liquor. If potassium fluoride be the precipitant, monohydrated **potassium thorium pentafluoride,** $KThF_5.H_2O$, is formed. J. J. Chydenius regarded it as a tetratahydrate, $KThF_5.\frac{1}{4}H_2O$. A. Rosenheim and co-workers obtained the anhydrous salt by melting thorium fluoride with an excess of potassium fluoride, and washing the cold mass with water until no more alkali fluoride dissolves. A. Duboin made it by heating to redness a soln. of thorium oxide in molten potassium hydrogen fluoride, and extracting the mass with water. H. L. Wells and J. M. Willis heated a soln. of thorium chloride with an aq. soln. of potassium hydrofluoride. J. J. Chydenius found that the weight of the salt is not changed at 150°; and A. Duboin, that it melts at a dull red heat. J. J. Chydenius, and A. Rosenheim obtained tetrahydrated **potassium thorium hexafluoride,** $K_2ThF_6.4H_2O$, by boiling thorium hydroxide with a soln. of potassium fluoride in the presence of hydrofluoric acid; or by boiling thorium fluoride with a soln. of potassium hydrofluoride. A litre of water at 25° was found by V. I. Spitzin to dissolve 0·4 mgrm. of thorium from $K_2ThF_6.4H_2O$. A. Kauffmann mentioned a complex $K_8Th_7F_{36}.6H_2O$. H. L. Wells and J. M. Willis add that "on account of the insolubility of thorium fluoride, and of these double salts, it is probable that there may be some doubt about the correctness of these formulæ." A. Rosenheim made trihydrated **rubidium thorium pentafluoride,** $RbThF_5.3H_2O$, by precipitation from a thorium salt soln. by one of rubidium hydrofluoride. On attempting to prepare *cæsium thorium fluoride,* H. L. Wells and J. M. Willis found that "thorium fluoride is practically insoluble even in conc. soln. of cæsium fluoride containing hydrofluoric acid. There is no doubt that the two fluorides combine under the circumstances, but since only finely divided precipitates were obtained there was no certainty as to their purity."

§ 8. Thorium Chlorides

As previously indicated, thorium when warmed unites vigorously with chlorine; and H. Moissan and A. Étard,[1] and H. Moissan and O. Hönigschmid made the chloride by heating thorium carbide or thorium containing carbide in a stream of chlorine. G. Krüss and L. F. Nilson prepared the chloride by heating the metal to low redness in a stream of dried hydrogen chloride, and subsequently resubliming the salt. H. Moissan and H. Martinsen found that thorium chloride is produced by the action of chlorine on thorium bromide.

J. J. Berzelius prepared anhydrous thorium chloride, $ThCl_4$, by the process used by H. C. Oersted for aluminium chloride. An intimate mixture of thoria and sugar was carbonized in a covered crucible, and the carbonaceous mass was heated in a porcelain tube through which passed a stream of chlorine. The reaction proceeds slowly. Most of the thorium chloride which is formed is deposited as a white, semi-fused mass just where the tube ceases to glow; when this mass is sublimed, brilliant, colourless crystals are produced. J. J. Chydenius, J. M. Matthews, and C. Baskerville employed modifications of this process. W. von Bolton, and C. A. Matignon and M. Delépine heated thoria in the vap. of carbon tetra-

chloride, and obtained an almost quantitative yield of thorium chloride; $ThO_2+2CCl_4=ThCl_4+2COCl_2$, or $ThO_2+CCl_4=ThCl_4+CO_2$. C. A. Matignon, and A. Duboin mixed the vapour of carbon tetrachloride with some chlorine. C. A. Matignon and M. Delépine also prepared thorium chloride by passing a mixture of carbon monoxide and chlorine over heated thoria, but found the reduction slow. E. Chauvenet, and C. Baskerville passed the vap. of carbonyl chloride over thoria at 650° : $ThO_2+2COCl_2=ThCl_4+2CO_2$. C. A. Matignon and F. Bourion, F. Bourion, H. von Wartenberg, and R. J. Meyer and A. Gumperz passed a mixture of chlorine and sulphur chloride vap. over thoria heated to 800°. The thorium chloride sublimes and condenses in the cooler part of the tube.

E. F. Smith and H. B. Harris heated eq. proportions of phosphorus pentachloride and thoria in an evacuated and sealed glass tube at about 240°. When the tube is opened, the phosphoryl chloride and phosphorus pentachloride can be distilled off. According to C. A. Matignon, the process is not a good one. E. Chauvenet found that thorium oxychloride is decomposed at a red heat, forming the dioxide and tetrachloride : $2ThOCl_2=ThO_2+ThCl_4$. The chloride can be separated from the oxide by sublimation. E. Chauvenet obtained the anhydrous chloride by treating hydrated thorium chloride with ammonium chloride and heating the product to 500°.

Anhydrous thorium chloride, purified by sublimation, furnishes colourless, prismatic **crystals** ; which, according to P. Groth, probably belong to the rhombic system. The crystals were examined by A. E. Nordenskjöld. H. Moissan and H. Martinsen found the **specific gravity** of the crystals to be 4·59. W. Biltz and E. Birk studied the mol. vol. I. I. Saslawsky gave 0·95 for the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements. According to F. E. Bartell and O. E. Madison, in the **osmosis** of soln. of thorium chloride the membrane becomes electropositive to the soln. ; the soln. side of the membrane is electropositive ; and the osmosis is positive. E. Chauvenet gave 0·407 for the **specific heat** between —23° and 17° ; and 149·8 for the mol. ht. K. Jauch found the sp. ht. of soln. with N eq. of thorium chloride per litre to be :

N	0·5	1·0	2·0	3·0	4·0
Sp. ht.	0·9443	0·8954	0·8118	0·7435	0·6860

J. J. Chydenius said that the salt melts in the gas blowpipe flame ; and H. Moissan and H. Martinsen gave 820° for the **melting point** of the salt. A. Voigt and W. Biltz gave 567° for the f.p., and 618° for the **boiling point.** J. J. Chydenius found no perceptible **volatilization** at 440°, but A. Duboin observed that volatilization occurs at a red heat ; and F. Bourion noted that in a stream of chlorine and sulphur chloride, volatilization is complete between 700° and 780°. G. Krüss and L. F. Nilson measured the **vapour density** of thorium chloride, and found (air unity):

	1057°	1102°	1140°	1270°	1400°
Vapour density	12·424	12·418	11·556	11·232	9·835

The theoretical density for $ThCl_4$ is 12·93. The vapour also dissociates at a temp. of about 400°. L. Troost made some observations which are vitiated by impurities in the samples used—*vide* the valency of thorium. According to E. Chauvenet, the heat of formation is 339·43 Cals., and, according to H. von Wartenberg, 300·2 ± 2·02 Cals. E. Chauvenet gave 56·75 Cals. for the heat of soln. at 12·5° ; and C. A. Matignon gave 53·80 Cals. per mol in 2700 mols of water at 18°—*vide infra* for the different hydrates. H. Moissan and H. Martinsen showed that the salt has a feeble **radioactivity.** A. E. Lindh studied the **X-ray absorption spectrum** of thorium chloride. A. Heydweiller measured the sp. gr. and **electrical conductivity** of soln. of thorium chloride ; and A. Voigt and W. Biltz, that of the molten chloride, which, at 814°, has a sp. conductivity of 0·61 mho ; at 866°, 0·71 mho ; and at 922°, 0·78 mho. B. Neumann and H. Richter gave 1·70 volts for the **decomposition voltage** of the chloride at 765°; the temp. coeff. is $1·875 \times 10^{-3}$.

H. Moissan and H. Martinsen said that the crystals are stable in light; and J. J. Berzelius, J. J. Chydenius, C. Baskerville, and H. Moissan and H. Martinsen remarked on the great **hygroscopicity** of the salt—E. Chauvenet said that 0·0183 grm. of water are absorbed from the atm. per gram per hour—but G. Krüss and L. F. Nilson, and C. A. Matignon and F. Bourion said that if the salt is well purified it is not markedly hygroscopic. The salt readily dissolves in **water** with the development of heat, forming a colourless soln. which, according to C. Baskerville, reacts acid. At a red heat, **oxygen** converts thorium tetrachloride into the dioxide. H. Moissan and H. Martinsen found that **fluorine** displaces the chlorine at ordinary temp., and if warmed, the mass becomes incandescent. W. Biltz and E. Meinecke found thorium chloride to be insoluble in liquid **chlorine.** A. Rosenheim and J. Schilling could not prepare **hydrochlorothoric acid,** H_2ThCl_6, but they obtained the pyridine chlorohydrate, $(C_5H_5N)_2H_2ThCl_6$, in well-defined crystals. This is considered to establish the existence of this acid. When heated in **sulphur** vap. and hydrogen, at a dark red heat, hydrogen chloride is formed, and thorium sulphide is produced; **selenium** vap. acts similarly. A. Duboin found that **hydrogen sulphide** reacts with the chloride at a dull red heat, forming thorium sulphide. For the action of ammonia, *vide infra.* H. Moissan and H. Martinsen found that at a red heat **phosphorus** forms a phosphide; neither **boron** nor **silicon** react with the chloride at 600°. Thorium chloride is reduced by **calcium ;** and, according to J. J. Berzelius, thorium chloride is decomposed by **potassium** " with a slight detonation and combustion." H. Moissan and H. Martinsen observed that molten **potassium nitrate** rapidly decomposes the chloride without incandescence, and that molten **potassium chlorate** behaves similarly. E. Chauvenet noted that a homogeneous liquid is obtained when thorium chloride is fused with **lithium chloride,** and complexes with the other **alkali chlorides** have been formed by fusion—*vide infra.* H. Moissan and H. Martinsen said that thorium chloride is insoluble in **carbon disulphide, chloroform, turpentine, toluene,** and **benzene ;** it is soluble in absolute **alcohol** and in 95 per cent. alcohol; it is soluble in water sat. with **ether.** C. Baskerville said that one part of the salt is soluble in 1000 parts of dried ether.

J. M. Matthews found that in addition to the octammine and the hexammine, thorium chloride forms addition compounds with **methyl-, ethyl-, propyl-,** and **β-naphthyl-amines,** and with **aniline, toluidine, pyridine,** and **quinoline ;** but not with **diphenylamine,** the **acid amides, nitrosyl chloride, nitrogen peroxide, sulphur monochloride,** the **phosphorus chlorides, cyanogen, dicyanogen, hydrogen cyanide, cyanogen chloride, acetonitrile, formonitrile,** or **benzonitrile.** Analogous results were obtained with the tetrachlorides of zirconium and lead, but not with titanium, and tin. A. Rosenheim and co-workers, and J. M. Matthews have obtained many compounds of thorium tetrachloride with organic bases, alcohol, etc., but not with ether.

Thorium tetrachloride forms a number of hydrates with water, but these have not yet been examined in the light of the phase rule. J. J. Berzelius noted that when a soln. of thorium hydroxide in hydrochloric acid is evaporated to a small bulk, it solidifies on cooling to a mass of radiating needle-like crystals, especially is this so if an excess of acid be present, for then the salt is less soluble. P. T. Cleve showed that the product is **octohydrated thorium tetrachloride,** $ThCl_4.8H_2O$. They are produced by allowing the aq. soln. to stand over sulphuric acid. According to P. T. Cleve, the product, dried over sulphuric acid, is either the hena- or the **dodecahydrated thorium tetrachloride,** $ThCl_4.12(or\ 11)H_2O$. G. Krüss and W. Palmaer obtained this hydrate by the crystallization of the heptahydrate from alcohol. A. Rosenheim and co-workers, and H. Moissan and H. Martinsen also obtained crystals of the octohydrate by evaporating an aq. soln. of the chloride at ordinary temp. E. Chauvenet gave for the heat of formation from the anhydrous salt, 45·25 Cals., and from the heptahydrate, 3·25 Cals. ; the heat of soln. of the octohydrate in water is 11·45 Cals. P. T. Cleve found the crystals deliquesce in

moist air. According to E. Chauvenet, the prismatic crystals lose no more than a mol of water in a desiccator at ordinary temp. and press., but in vacuo over sulphuric acid, four mols of water are given off, and on a water-bath, six mols. If the temp. exceeds 100°, an oxychloride, $Th(OH)Cl_3.H_2O$, is first formed, then $ThOCl_2$, and finally thorium dioxide. J. J. Berzelius noted that the aq. soln. becomes turbid when boiled, owing to hydrolysis; he also noted that the salt is very soluble in water and in alcohol. J. J. Chydenius stated that the soln. gives no precipitate with potassium dichromate. E. Chauvenet found that when the octohydrate is heated on a water-bath, it furnishes **dihydrated thorium tetrachloride**, $ThCl_4.2H_2O$, and that the heat of formation from the anhydrous salt is 15·62 Cals., and the heat of soln., 41·08 Cals. If the octohydrate be slowly heated in a current of hydrogen or dry hydrogen chloride, or if it is allowed to stand several days in vacuo, **tetrahydrated thorium tetrachloride,** $ThCl_4.4H_2O$, is formed. The heat of formation from the anhydrous chloride is 30·47 Cals., and from the dihydrate, 14·85 Cals., the heat of soln. is 26·23 Cals. According to E. Chauvenet, if the octohydrate be dried to a constant weight in a dry atm., **heptahydrated thorium tetrachloride,** $ThCl_4.7H_2O$, is formed. He also said that this hydrate is produced by A. Rosenheim and J. Schilling's method for $Th(OH)Cl_3.11H_2O$—*vide infra.* G. Krüss and W. Palmaer prepared the heptahydrate by treating thorium hydroxide suspended in absolute alcohol with hydrogen chloride, and allowing the soln. thus obtained to crystallize in a vacuum over sodium hydroxide and sulphuric acid. It crystallizes in rhombic pyramids, deliquesces in the air, and effloresces when allowed to remain in a desiccator, water and hydrogen chloride being given off. The anhydrous chloride cannot be prepared by heating the crystals in a current of hydrogen chloride or chlorine, as under these conditions a mixture containing oxychloride is obtained. When heated, it decomposes with formation of thorium oxide and evolution of water and hydrogen chloride. It is very easily soluble in water and alcohol, yielding an acid soln., and the addition of ether to the alcoholic soln. causes a precipitate of the unaltered salt. E. Chauvenet added that when heated in a stream of dry hydrogen chloride the oxychloride $Th(OH)Cl_3.H_2O$ is formed. The heat of formation from the anhydrous chloride is 42·00 Cals., and from the tetrachloride 11·53 Cals.; the heat of soln. is 14·75 Cals. at 13·5°. According to A. Rosenheim and co-workers, G. Krüss and W. Palmaer's process just described furnishes **enneahydrated thorium tetrachloride,** $ThCl_4.9H_2O$; but E. Chauvenet could not prepare this hydrate; nor could W. Biltz and E. Keunecke prepare a sulphohydrate, $ThCl_4.nH_2S$.

According to J. J. Berzelius,[2] in the preparation of the anhydrous chloride by the action of chlorine on a mixture of thoria and carbon, a white cloud passes along with the chlorine gas, and condenses in the receiver as a white amorphous sublimate, assumed to be a thorium oxychloride because water resolves it into soluble thorium chloride, and thoria. J. J. Chydenius, however, regarded the cloud as thorium chloride. C. A. Matignon and M. Delépine found that **thorium oxychloride**, or *thoryl chloride,* $ThOCl_2$, is an intermediate compound in the preparation of the tetrachloride by the action of carbon tetrachloride, or a mixture of chlorine and carbon monoxide on heated thoria; and they isolated it by stopping the reaction when the product contains $ThO_2 : ThCl_4 = 1 : 8$ or 9, and extracting the cold mass with absolute alcohol. The oxychloride is then obtained as a residue of small colourless needles. E. Chauvenet obtained it by heating heptahydrated thorium tetrachloride to 250° in a stream of hydrogen chloride, but G. Krüss and W. Palmaer could not make it at temp. between 150° and bright red heat. They said that the preparation of a pure compound of the composition $ThOCl_2$ has not been accomplished; nothing but impure products were obtained by heating the chloride in a current of hydrogen chloride or chlorine, or by heating the hydroxide in a current of hydrogen chloride. The product obtained by heating the crystalline chloride alone always contains more thorium oxide than is required by the above formula. According to C. A. Matignon, and W. Palmaer, the white needle-like

crystals are very hygroscopic; readily soluble in water, insoluble in absolute alcohol; R. J. Meyer also said the salt is soluble in water, while H. Karstens said it is insoluble in this menstruum. E. Chauvenet said that the heat of soln. in water is 28·15 Cals. at 13°.

A. Rosenheim, V. Samter, and J. Davidsohn obtained white acicular crystals of **pentahydrated thorium dihydroxydichloride,** $Th(OH)_2Cl_2.5H_2O$, by treating freshly precipitated·thorium hydroxide with alcohol sat. with hydrogen chloride, and evaporating off the alcohol first on a water-bath, and then in vacuo over sulphuric acid. The crystals are fairly stable in air, readily soluble without decomposition in water and in alcohol. According to C. A. Matignon and M. Delépine, if the evaporation be allowed to proceed further, the *tetrahydrate,* $Th(OH)_2Cl_2.4H_2O$, is formed. They also found that if thorium oxychloride be allowed to stand at 10° to 15° in an atm. sat. with water vap., water corresponding with $ThOCl_2.6H_2O$, *i.e.* the pentahydrate $Th(OH)_2Cl_2.5H_2O$ is absorbed; and if this product be allowed to stand in a dry place, $ThOCl_2.5H_2O$, *i.e. the tetrahydrate,* $Th(OH)_2Cl_2.4H_2O$, is formed. If the cold soln. of thorium hydroxide in the alcoholic soln. of hydrogen chloride be evaporated in the cold under reduced press., 50 mm., over sulphuric acid and potassium hydroxide, A. Rosenheim and J. Schilling found that the *octohydrate,* $Th(OH)_2Cl_2.8H_2O$, is formed.

According to A. Rosenheim, V. Samter, and J. Davidsohn, if freshly precipitated thorium hydroxide be dissolved in an alcoholic soln. of hydrogen chloride, but not sat., white leaflets of **heptahydrated thorium hydroxytrichloride,** $Th(OH)Cl_3.7H_2O$, separate on evaporation. By distilling the alcohol almost completely from the alcoholic soln. of octohydrated thorium dihydroxydichloride, digesting the syrupy residue with hydrochloric acid of sp. gr. 1·12, and evaporating the soln. over conc. sulphuric acid, A. Rosenheim and J. Schilling obtained the *henahydrate,* $Tl(OH)Cl_3.11H_2O$; but E. Chauvenet said that heptahydrated thorium tetrachloride is formed under these conditions. According to the last-named, when the latter salt is heated between 120° and 160° to constant weight in a stream of hydrogen chloride, *the monohydrate,* $Tl(OH)Cl_3.H_2O$, is produced. If the temp. be 100°, a hydrated product intermediate between $Tl(OH)_2Cl_2$ and $Tl(OH)Cl_3$ is formed. · The monohydrate is very deliquescent, and has a heat of dissolution 47·63 Cals. at 13·5°. E. Chauvenet prepared **lithium thorium oxychloride,** $LiThOCl_3$ by heating $LiThCl_5.8H_2O$ to 400° in a stream of dry hydrogen chloride. Towards 800°, the salts decompose and thorium and lithium chlorides volatilize, leaving thoria behind. E. Chauvenet also found that if the double chloride of thorium and lithium be heated to 200°, it forms **lithium thorium hydroxytrichloride,** $LiCl.Th(OH)Cl_3$; similarly the potassium salt furnishes **potassium thorium hydroxytrichloride,** $KCl.Th(OH)Cl_3$; and the sodium salt, **sodium thorium hydroxytrichloride,** $NaCl.Th(OH)Cl_3$. If the temp. exceeds 200°, a mixture of thoria, thorium tetrachloride, and the alkali chloride is formed. G. Wyrouboff and A. Verneuil assume that a hydrated *thorium peroxychloride,* $Th_2O_7Cl_2.nH_2O$, is formed by the action of hydrogen peroxide on the normal chloride.

According to H. P. Stevens, when thorium meta-oxide, prepared from the oxalate, is treated with dry hydrogen chloride, it is converted into an oxychloride which contains chlorine varying from 0·61 to 10 per cent., dependent on the amount of water contained in the thorium meta-oxide. Thorium meta-oxide, like silicic acid, retains water persistently, but when it is dried by heating in a current of dry air it is no longer acted on by hydrogen chloride. The reaction which takes place between the oxide containing water and chlorine corresponds with the formula $ThO_2,xThCl_4$ for the oxychloride. **Thorium meta-oxychloride** is a white, hygroscopic powder which dissolves in water to a clear soln. when it contains 9 to 10 per cent. of chlorine; the preparations with less chlorine yield a more or less opalescent soln. It has an acid reaction, is insoluble in absolute alcohol, dissolves in alcohol containing a small quantity of water, behaves towards reagents in a similar manner to metastannic chloride, and is precipitated by many normal salts and

by excess of acid, this precipitation taking place more easily the less chlorine it contains. When treated with silver nitrate, it does not give a precipitate of silver chloride.

G. Wyrouboff and A. Verneuil prepared a series of **hydrochlorides of thorium meta-oxide.** Partially dehydrated thorium hydroxide was digested in water, and hydrochloric acid added drop by drop until no further precipitate was formed. The less the hydroxide is heated the more hydrochloric acid is required for this purpose. The liquid was decanted from the precipitate, and the latter again treated with water and acid. The product was washed with water until the filtrate gave no precipitate with ammonia. The product gives an opalescent liquid when digested with water, the soln. has an acid reaction; silver nitrate gives no precipitate. The soln. is flocculated by dil. sulphuric acid, or neutral sulphates. The precipitate is insoluble in water. The product thus behaves like a typical colloid. The ratios $ThO_2 : Cl : H_2O$ in the product are very variable; the more strongly the calcination of the original hydroxide, the smaller the proportion of chlorine. G. Wyrouboff and A. Verneuil claimed to have made a series of hydrated **thorium hydroxyhydrochlorides,** $24ThO_2.4HCl.6H_2O$, which is dehydrated without decomposition at $250°$; $10ThO_2.4HCl.11H_2O$, which loses nine mols of water at $130°$; and $Th_8O_7(OH)_{16}Cl_2.2HCl$. W. von Bolton also reported $10ThO_2.4HCl$ to be formed when powdered thorium is shaken with cold, 5 per cent. hydrochloric acid, the first portion which dissolves (about 10 per cent. of the whole metal) forms a complex acid, $(ThO_2)_{10}(HCl)_4$, the soln. of which contains neither thorium nor chlorine ions; its principal reactions are: with oxalic acid or sulphuric acid, a small precipitate, soluble in excess, is produced; ammonium oxalate gives a gelatinous precipitate, insoluble on boiling; ammonium carbonate and citric acid give gelatinous precipitates, insoluble in excess. R. J. Meyer, and H. Karstens have discussed W. von Bolton's observations and consider that the thorium was contaminated with some meta-oxide. W. Biltz and E. Keunecke found that dry, liquid hydrogen sulphide does not react with or dissolve thorium tetrachloride at $-78.5°$.

H. Moissan and H. Martinsen [3] found that when the thorium chloride is treated with liquid ammonia, a complex is formed which is sparingly soluble in that menstruum. Addition compounds of thorium chloride have been obtained with ammonia, methylamine, ethylamine, propylamine, aniline, toluidine, pyridine, quinoline, and β-naphthylamine. It also forms crystalline addition compounds with alcohol, $ThCl_4.4C_2H_5OH$; acetaldehyde, $ThCl_4.2CH_3CHO$; acetone, $ThCl_4.2CH_3COCH_3$; cinnamic aldehyde; benzaldehyde; salicyl aldehyde; etc. These compounds have been studied by J. M. Matthews, and A. Rosenheim and co-workers. E. Chauvenet divides the **thorium amminochlorides** into three groups: (i) Those formed by the action of dry liquefied ammonia on thorium chloride and the subsequent evaporation of the excess of ammonia at different temp. and under different conditions. The members of this group are represented by the formula $Th(NH_3)_nCl_4$; (ii) The compounds formed by leaving the chloride in contact with gaseous ammonia at ordinary temp. (or warmed) are regarded as $Th(NH_3Cl)_4$ or $Th(NH_3Cl)\{NH_2(NH_4)Cl\}_3$; and (iii) the compounds formed by the action of liquid ammonia on the members of the second group. Their composition is represented by $Th(NH_3Cl)_4.nNH_3$. The approximate temp. of formation and dissociation at ordinary press.; the heat of formation (Cals.) from thorium tetrachloride; and the heat of dissolution (Cals.) in hydrochloric acid are shown in Table V. The hexa- and the hepta-ammines in the last two series are identical; hence there remain ten compounds or five pairs of isomeric compounds. The higher members of the first series rapidly lose ammonia, forming the tetrammine. They are all decomposed by water. The members of the second series are not decomposed in vacuo or when treated with water; and in the third series, the dodeca- and the octodeca-ammines are decomposed in vacuo or by water. The temp. of dissociation at 100 mm. press. are by G. L. Clark.

TABLE V.—THE AMMONIA COMPOUNDS OF THORIUM CHLORIDE.

General formula.	Compound.	Temp. of formation and dissociation.	Temp. of dissociation at 100 mm. press.	Heat of formation from ThCl₄.	Heat of dissolution in HCl.
ThCl₄.nNH₃	ThCl₄.4NH₃	15° in vacuo	305°	80	61·7
	ThCl₄.6NH₃	45°	168°	111·06	73·14
	ThCl₄.7NH₃	15°	84°	122·7	82·75
	ThCl₄.12NH₃	−5°	17°	172	139·7
	ThCl₃.18NH₃	−23°	1°	225	214·2
Th(NH₃Cl)₄	ThCl₄.4NH₃	120° (5 days)	406°	104·4	37·3
	ThCl₄.6NH₃	90°–100° (month)	—	148·7	35·5
	ThCl₄.7NH₃	20° (25 days)	—	169·43	36·02
Th(NH₃Cl)₄.nNH₃	ThCl₄.6NH₃	55°	362°	148·9	35·3
	ThCl₄.7NH₃	20°	323°	171·3	34·15
	ThCl₄.12NH₃	−5°	31°	218	93·7
	ThCl₄.18NH₃	−23°	−20°	267·3	171·9

According to E. Chauvenet, **thorium tetramminochloride**, $ThCl_4.4NH_3$, and $Th(NH_3Cl)_4$—*vide supra*—give *thorium tetramide*, $Th(NH_2)_4$ and hydrogen chloride at 250°–300°; at a red heat, *thorium diimide*, $Th(NH)_2$, and ammonia; and at a still higher temp., the nitride is probably formed. J. M. Matthews prepared **thorium hexamminochloride**, $ThCl_4.6NH_3$—according to E. Chauvenet: $Th(NH_3Cl)_4.2NH_3$—by passing ammonia over thorium tetrachloride. Much heat is developed, and the white product fumes in air. E. Chauvenet's work on the two isomers is summarized in Table I; similarly also with the isomeric forms of **thorium heptamminochloride**, $ThCl_4.7NH_3$, and $Th(NH_3Cl)_4.3NH_3$. J. M. Matthews prepared **thorium octamminochloride**, $ThCl_4.8NH_3$, as a white flocculent mass, by passing dry ammonia into a soln. of thorium chloride in desiccated ether. The dried product is stable. The properties of E. Chauvenet's isomeric forms of **thorium dodecamminochloride**, $ThCl_4.12NH_3$, and $Th(NH_3Cl)_4.8NH_3$, are indicated in Table I. E. Chauvenet made the two isomers of **thorium octodecamminochloride**, $ThCl_4.18NH_3$, and $Th(NH_3Cl)_4.14NH_3$, as indicated above. The former was also made by passing ammonia gas through a tube reaching to the bottom of a small distillation flask with a constricted neck containing anhydrous thorium chloride, a long manometer tube containing a mercury index being sealed to the side-tube. The air being displaced, the flask was immersed in acetone and snow until a quantity of liquid ammonia had accumulated. The excess was then evaporated by placing the flask in liquid methyl chloride. The neck was then sealed off, at the same time the necessary mercury being poured into the gauge. The dissociation press., p, of the octodecammine is:

	−22·5°	−10°	0°	8°
Dissociation pressure . .	246	560	1031	1630 mm.

The heat of formation of the octodecammine from the dodecammine is 8.83×6 Cals. The sp. ht. is 0·524 per gram. The value of the heat of formation, Q, computed from Clapeyron's equation and the calculated values of p agree closely with the observed values.

A number of complex salts have been prepared. J. J. Chydenius [4] mixed ammonium chloride with a soln. of thorium oxide in hydrochloric acid, and after evaporation to dryness, he heated the dry mass in hydrogen chloride and obtained a crystalline mass which he regarded as *ammonium thorium dodecachloride*, $(NH_4)_8ThCl_{12}.8H_2O$, but G. Krüss and W. Palmaer could not confirm the existence of such a compound. E. Chauvenet obtained crystals of **ammonium thorium hexachloride**, $(NH_4)_2ThCl_6.10H_2O$, from a soln. containing 3 mols of ammonium chloride to one mol of thorium chloride. The heat of soln. is —3·9 Cals. When

this compound is heated to 150°, **ammonium thorium pentachloride,** NH_4ThCl_5, is produced. It furnishes thorium tetrachloride at 500°. The heat of formation is 13·12 Cals., and the heat of soln., 39·82 Cals.

E. Chauvenet prepared **lithium thorium hexachloride,** $ThCl_4.2LiCl$, by melting two mols of lithium chloride with one mol of thorium chloride. The heat of formation is 4·67 Cals., and the heat of soln., 68·83 Cals. E. Chauvenet inferred that combination occurred because of the difference in the heats of soln. of the product and of the sum of the component chlorides ; with this test, no combination occurred with equi-molar proportions of the two chlorides to form $LiThCl_5$. By evaporating mixed soln. of the component salts, he obtained octohydrated **lithium thorium pentachloride,** $LiThCl_5.8H_2O$. The heat of formation is 37·65 Cals. The heat of soln. is 25·2 Cals. The salt cannot be dehydrated by heat because in a stream of dry hydrogen chloride at 200°, the oxychloride $LiTh(OH)Cl_4$ is formed. As in the case of lithium, E. Chauvenet could prepare only **sodium thorium hexachloride,** Na_2ThCl_6, by the fusion process. The heat of formation is 4·3 Cals., and the heat of soln. 50·04 Cals. He also made decahydrated **sodium thorium pentachloride,** $NaThCl_5.10H_2O$, as in the case of the octohydrated lithium salt. The heat of formation is 37·65 Cals., and the heat of soln., −5·74 Cals. It yields the oxychloride $NaTh(OH)Cl_4$ at 200° in a stream of hydrogen chloride.

J. J. Berzelius described the preparation of a double salt by heating a dried mixture of the component salts in a stream of hydrogen chloride, and by crystallization from aq. soln. P. T. Cleve evaporated the mixed soln. of equi-molar proportions of the component salts and obtained a crop of crystals of potassium chloride, followed by one of colourless crystals of **potassium thorium enneachloride,** $KTh_2Cl_9.18H_2O$. The crystals lose 7·1 per cent. of water when dried over sulphuric acid. The salt is very soluble in water. J. J. Berzelius thought that the salt can be dehydrated in a stream of hydrogen chloride, but in view of E. Chauvenet's work this is doubtful. L. F. Nilson, and H. Moissan and O. Hönigschmid obtained a double salt by evaporating a soln. of two mols of potassium chloride to one mol of thorium chloride. The product does not appear to have been analyzed. E. Chauvenet prepared **potassium thorium hexachloride,** K_2ThCl_6, by the same process as that employed for the lithium salt. The heat of formation is 9·14 Cals., and the heat of soln., 39·12 Cals. He also made enneahydrated **potassium thorium pentachloride,** $KThCl_5.9H_2O$, by crystallization from a soln. containing three mols of potassium chloride to one mol of thorium chloride. The heat of formation is 37·65 Cals., and the heat of soln., 3·5 Cals. While the five alkali chlorides when fused in the right proportions furnish double salts of the type $2MCl.ThCl_4$, cæsium and rubidium chlorides in addition furnish salts of the type $4MCl.ThCl_4$. E. Chauvenet prepared **rubidium thorium octochloride** Rb_4ThCl_8, with a heat of formation 26·3 Cals., and a heat of soln., 10·65 Cals., and **rubidium thorium hexachloride,** Rb_2ThCl_6, with a heat of formation 19·3 Cals., and a heat of soln., 27·5 Cals. A mixed soln. of two mols of rubidium chloride and one mol of thorium chloride yields crystals of the *enneahydrate*, $Rb_2ThCl_6.9H_2O$, with a heat of formation 26·9 Cals., and a heat of soln., 0·6 Cal. It loses water in a stream of dried hydrogen chloride at 150°. E. Chauvenet's **cæsium thorium octochloride,** Cs_4ThCl_8, has a heat of formation from the component salts of 18·11 Cals., and a heat of soln., 19·79 Cals. ; and **cæsium thorium hexachloride,** Cs_2ThCl_6, prepared like the lithium salt, has a heat of formation 14·9 Cals., and a heat of soln. 32·46 Cals. An aq. soln. of two mols of cæsium chloride and one mol of thorium chloride gives crystals of the *octohydrate*, $Cs_2ThCl_6.8H_2O$, with a heat of formation 29·86 Cals., and a heat of soln. 2·6 Cals. The water of crystallization is lost in a stream of dry hydrogen chloride at 150°. According to H. L. Wells and J. M. Willis, a mixed soln. of 65 grms. of thorium chloride and 30 to 100 grms. of cæsium chloride in hydrochloric acid gives small, colourless, hygroscopic crystals of the *henahydrate*, $Cs_2ThCl_6.11H_2O$, which gradually lose their water of crystallization in a desiccator over sulphuric acid. They also reported colourless hygroscopic crystals of

the *dodecahydrate*, $Cs_2ThCl_6.12H_2O$, derived from a soln. containing 12 grms. of thorium chloride, and 30–110 grms. of cæsium chloride.

§ 9. Thorium Bromides

As previously indicated, thorium unites directly with bromine to form **thorium bromide**, $ThBr_4$. H. Moissan and H. Martinsen [1] prepared the anhydrous bromide by passing dried bromine vap. over thorium carbide as in the analogous preparation of thorium chloride. The sublimate was re-sublimed in a stream of hydrogen, and then in vacuo. L. Troost and L. Ouvrard prepared the bromide by H. C. Oersted's reaction indicated in connection with the chloride, *i.e.* by passing bromine vap. over a red-hot mixture of thoria and carbon. F. Bourion made the anhydrous bromide by passing a mixture of sulphur monochloride vap. and hydrogen bromide over thoria heated not above a red heat, and subliming in hydrogen bromide. According to L. Troost and L. Ouvrard, the white acicular crystals are very hygro-

scopic. H. Moissan and H. Martinsen found the sp. gr. of the crystals to be 5·62, and that of the white vitreous solid, 5·67. W. Biltz and E. Birk studied the mol. vol. I. I. Saslawsky gave 0·99 for the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements. The crystals melt and volatilize more readily than do those of the chloride. Sublimation begins between 600° and 620° ; volatilization is complete at 700° ; the b.p. is 725°. The salt is feebly radioactive.

Thorium bromide in a sealed tube slowly decomposes when exposed to **light,** and it acquires a grey colour owing to the separation of bromine. The salt is attacked by **fluorine** at ordinary temp., and the warm bromide is attacked by **chlorine.** A. Rosenheim and J. Schilling could not isolate **hydrobromothoric acid,** H_2ThBr_6, but they obtained a crystalline compound of this acid with pyridine hydrochloride. H. Moissan and H. Martinsen found that when heated in **oxygen,** thorium bromide gives off bromine and forms thorium dioxide; at a dull red heat, **hydrogen sulphide** forms thorium sulphide, and **hydrogen selenide,** thorium selenide. The bromide at a dull red-heat is reduced by **calcium.**

Thorium bromide is very soluble in **water,** and, according to L. Troost and L. Ouvrard, there is a partial hydrolysis with the formation of an acidic soln., and an insoluble precipitate. H. Moissan and H. Martinsen noted that when the aq. soln. is boiled in air, thorium oxybromide, $ThOBr_2$, is formed. E. Chauvenet gave 70·19 Cals. for the heat of soln. A number of hydrates has been reported, but they have not been tested by the phase rule. J. J. Berzelius obtained a gummy mass by evaporating at ordinary temp. a soln. of thorium hydroxide in hydrobromic acid. E. Chauvenet considers the product to have been an oxybromide. A. Rosenheim and J. Schilling reported **heptahydrated thorium tetrabromide,** $ThBr_4.7H_2O$, to be formed, in acicular crystals, by the evaporation of the mother-liquor remaining after the preparation of henahydrated thorium dihydroxydibromide. E. Chauvenet gave 47·64 Cals. for the heat of formation from the anhydrous bromide, and 22·55 Cals. for the heat of soln. H. Moissan and H. Martinsen prepared **octohydrated thorium tetrabromide,** $ThBr_4.8H_2O$, by allowing the aq. soln. to stand over sulphuric acid. J. Lesinsky and C. Gundlich prepared the same salt by dissolving thorium hydroxide in hydrobromic acid and allowing the soln. to stand in darkness over sulphuric acid in vacuo: The product was washed with ligroïn and chloroform, and recrystallized from alcohol. E. Chauvenet claimed that these processes give the heptahydrate not the octohydrate. The crystals absorb carbon dioxide from atm. air ; they melt at 100°, and give off all their water at a higher temp. The salt is very soluble in water and alcohol. E. Chauvenet obtained needle-like crystals of **dodecahydrated thorium tetrabromide,** $ThCl_4.12H_2O$, by evaporating on a water-bath a soln. of thorium hydroxide in alcoholic hydrogen bromide, and drying the product on a porous tile. The heat of formation is 67·89 Cals., and the heat of soln., 2·30 Cals. In dry air, **decahydrated thorium tetrabromide,** $ThBr_4.10H_2O$, is formed. A. Rosenheim and co-workers made the decahydrate by crystallization from a soln. of thorium hydroxide in alcoholic hydrogen bromide ; and P. Jannasch and co-workers, by concentrating over sulphuric acid, in vacuo, a soln. of thorium hydroxide in hydrobromic acid. The needle-like or prismatic crystals are very hygroscopic and decompose if left in contact with moist air. E. Chauvenet gave 60·35 Cals. for the heat of formation from the anhydrous bromide, and 9·84 Cals. for the heat of soln. The salt loses some hydrogen at 100°. The crystals are very soluble in water and in alcohol.

As indicated above, aq. soln. of thorium bromide are readily hydrolyzed. and oxybromides are formed. Thus, said E. Chauvenet, when a soln. of thorium bromide is evaporated, as in J. J. Berzelius' mode of preparation, *vide supra,* the product approximates in composition $ThBr_4.Th(OH)Br_3.16H_2O$. A. Rosenheim and co-workers obtained crystals of decahydrated **thorium hydroxytribromide,** $Th(OH)Br_3$, from an alcoholic soln. of hydrogen bromide not completely sat. with thorium hydroxide. H. Moissan and H. Martinsen obtained **thorium oxydibromide,** $ThOBr_2$, by boiling an aq. soln. of thorium bromide exposed to air, and drying the

product at 160°; F. Bourion obtained it by passing a slow current of sulphur mono-chloride mixed with hydrogen bromide over thoria at 125°. The white amorphous powder so obtained is soluble in water. A. Rosenheim and co-workers made the *tetrahydrate* of **thorium dihydroxydibromide,** $Th(OH)_2Br_2.4H_2O$, by evaporating in vacuo over conc. sulphuric acid, alcoholic hydrogen bromide completely sat. with thorium hydroxide. The white microscopic needles are fairly stable in air, but slowly lose hydrogen bromide. The salt is easily soluble in water and in alcohol. A. Rosenheim and J. Schilling obtained small quadratic crystals of the *henahydrate,* $Th(OH)_2Br_2.11H_2O$, from a soln. of thorium hydroxide in alcoholic hydrogen bromide, sat. in the cold, and evaporated slowly over sulphuric acid and potassium hydroxide.

J. M. Matthews, and A. Rosenheim and co-workers prepared a number of complexes of thorium bromide with ammonia and the substituted ammonias, pyridine, aniline, etc. According to H. Moissan and H. Martinsen, thorium tetra-bromide dissolves in liquid ammonia at —40°, and forms an ammino-compound. J. M. Matthews reported **thorium triamminobromide,** $ThBr_4.3NH_3$, to be formed by passing dry ammonia over warmed thorium bromide. J. J. Berzelius reported *potassium thorium bromide* to be formed from mixed soln. of the component salts.

§ 10. Thorium Iodides

L. F. Nilson,[1] and H. Moissan and A. Étard obtained anhydrous **thorium tetraiodide,** ThI_4, by burning thorium in iodine vap. J. J. Chydenius evaporated thorium hydroxide in a soln. of hydriodic acid, and obtained a gummy mass which turned brown on exposure to air. P. Jannasch and co-workers, and J. Lesinsky and co-workers obtained similar results, and they also obtained prismatic crystals so unstable that no analyses were made. The salt is decomposed on heating, or on exposure to light with the evolution of iodine. W. Biltz and E. Birk studied the mol. vol. A. Rosenheim and co-workers prepared acicular or prismatic crystals of **decahydrated thorium tetraiodide,** $ThI_4.10H_2O$, from the mother-liquor remaining after the preparation of **decahydrated thorium hydroxytriiodide,** $Th(OH)I_3.10H_2O$, which is formed by saturating an alcoholic soln. of hydrogen iodide with thorium hydroxide, and allowing the soln. to crystallize in the dark in vacuo over sulphuric acid. This compound slowly decomposes into hemihepta-hydrated thorium oxydiiodide, $ThOI_2.3\frac{1}{2}H_2O$, which then changes to white anhydrous thorium oxydiiodide, $ThOI_2$, and this, in turn, becomes yellow on exposure to light.

According to A. Duboin, when thorium iodide, prepared by the action of hydriodic acid on thorium carbonate, and mercuric iodide are alternately dissolved in water at a gentle heat to saturation, the liquid on cooling deposits, first, mercuric iodide and then a mass of extremely deliquescent crystals of **mercuric thorium tetradecaiodide,** $Hg_5ThI_{14}.18H_2O$ or $ThI_4.5HgI_2.18H_2O$, easily decomposed by water, and quickly changed by exposure to air, becoming red. The mother-liquor is dark brown in colour, owing to the presence of free iodine, and the latter is removed by shaking with mercurous iodide, giving a yellow liquid of sp. gr. 3·512

at 18·90°; its composition corresponds with $Hg_5Th_2I_{18}.21H_2O$. When this liquid is evaporated, filtered from the mercuric iodide which separates, and again evaporated, it furnishes crystals of **mercuric thorium octoiodide**, $Hg_2ThI_8.12H_2O$.

§ 11. Thorium Sulphides

J. J. Berzelius,[1] L. F. Nilson, H. von Wartenberg, etc., made **thorium sulphide,** ThS_2, by the action of sulphur or hydrogen sulphide on heated thorium. H. Moissan and A. Étard also prepared this sulphide by passing the vap. of sulphur over heated thorium carbide; and G. Krüss and C. Volck, by heating a mixture of thorium chloride and potassium chloride in a stream of dry hydrogen sulphide. A. Duboin thus describes the preparation :

When a mixture of thorium chloride with an excess of sodium or potassium chloride, contained in a porcelain boat, is heated in a current of dry hydrogen sulphide, the product, after washing out the alkali chloride, consists chiefly of brown, micaceous lamellæ, together with small quantities of yellow crystals and of an amorphous substance. The brown lamellæ of thorium sulphide can be isolated by means of a sieve.

E. Kunheim used a similar process, but added diatomaceous earth or asbestos to the mixture to be heated in the hydrogen sulphide. J. J. Chydenius passed a mixture of hydrogen and the vap. of carbon disulphide over thorium meta-oxide at a white heat and claimed to have made thorium sulphide, but G. Krüss said that thorium oxysulphide, ThOS, not thorium sulphide, is formed, and E. W. von Siemens and J. G. Halske said that the product contains carbon. To eliminate this, they recommended using a mixture of hydrogen sulphide and carbon disulphide in place of the last-named vap. and hydrogen. A. E. van Arkel and J. H. de Boer made the sulphide by passing the vapour of the chloride mixed with hydrogen sulphide over a heated tungsten filament.

Pulverulent thorium sulphide, prepared by the different processes, has a yellow colour; L. F. Nilson, and H. Moissan and A. Étard's preparations were black; and A. Duboin's dark brown, lamellar crystals. J. J. Chydenius gave 8·29 for the sp. gr., but this number is probably too high, because H. von Wartenberg obtained 6·8, and A. Duboin 6·7 at 0° for this constant. The last-named also said that the crystals act feebly on polarized light. The crystals burn with a blue flame when heated in air; and J. J. Berzelius said that when heated in a tube, the sulphur may be distilled off, and thorium oxide remains. H. von Wartenberg said that the compound is stable in water and soln. of the alkali hydroxides, even when boiled; and with hot dil. acids, sulphur separates out. J. J. Chydenius found that the compound is not changed when heated in hydrogen; when fused with potassium hydroxide it forms thorium oxide and potassium sulphide; and with hydrochloric acid, it forms thorium chloride. J. J. Berzelius added that with dil. sulphuric acid, some hydrogen sulphide is at first evolved, without dissolution; hydrochloric acid and nitric acid attack it a little; and hot aqua regia oxidizes the sulphide to sulphate. A. Duboin said that the brown crystals are violently attacked by nitric acid.

As indicated above, A. Duboin obtained a mixture of brown plates and small quantities of a yellow substance, when thorium and sodium chlorides are heated

in hydrogen sulphide. When the mixed product is treated with nitric acid, at 40°, the brown plates are vigorously attacked, while the yellow crystals are attacked slowly. He found that the yellow crystals are **thorium oxysulphide,** or *thoryl sulphide,* ThOS. G. Krüss obtained thorium oxysulphide by a similar process; and by the action of carbon disulphide on heated thoria. O. Hauser also made it by heating anhydrous thorium sulphate at 380°–400°, in a stream of dry air to remove the last trace of moisture, and then to redness in a current of hydrogen sulphide; after two hours the product is cooled in a stream of the same gas. The oxysulphide obtained by these processes is a brown or black powder; but that prepared by A. Duboin is in the form of orange-yellow crystals which resemble pyrites. O. Hauser gave 6·44 for the sp. gr., and A. Duboin, 8·42 at 0°. The latter said that the crystals are uniaxial and optically negative. According to O. Hauser, the oxysulphide inflames spontaneously when exposed to air. When heated in air or oxygen, thoria is formed. G. Krüss found that the compound is soluble in aqua regia, but, according to A. Duboin,co nc. nitric acid attacks the oxysulphide very slowly. J. J. Chydenius also described a compound *thorium tetroxydisulphide,* $2ThO_2.ThS_2$, which he obtained by the action of a mixture of hydrogen and carbon disulphide on thoria obtained by igniting the hydroxide at a low temp. G. Krüss and C. Volck, however, denied the existence of the compound which they regarded as a mixture of thorium sulphide, carbonyl sulphide, and unchanged thoria.

§ 12. Thorium Sulphates

J. J. Berzelius [1] made anhydrous **thorium sulphate,** $Th(SO_4)_2$, by digesting finely divided thoria with a mixture of sulphuric acid (2 : 1) for several hours, and removing the excess of acid by evaporation. G. Krüss and L. F. Nilson, and R. J. Meyer and A. Gumperz showed that there is a condition of equilibrium between the temp. and the proportion of normal, basic, or acid sulphate. L. F. Nilson obtained the anhydrous sulphate by dehydrating one of the hydrates—according to P. T. Cleve, the temp. of calcination should be below redness; and, according to G. Krüss and L. F. Nilson, G. Wyrouboff, and R. J. Meyer and A. Gumperz, about 400°. The white, earthy product is, according to G. Wyrouboff, microcrystalline. G. Krüss and L. F. Nilson gave 4·2252 (17°) for the sp. gr.; and L. F. Nilson and O. Pettersson, 0·0972 for the sp. ht., and 41·21 for the mol. ht. L. and P. Wöhler and W. Plüddemann found the vap. press. of the sulphur trioxide in equilibrium with oxygen and sulphur dioxide to be :

	575°	610°	660°	698°	720°	755°	785°
Vap. press. . .	.16	32	44	80	144	198	344 mm.

Both mols of sulphur trioxide have the same vap. press., so that there is no evidence of the formation of a basic salt. The heat of dissociation is 21 cals. According to P. T. Cleve, at a red heat, the sulphate loses all its sulphur trioxide. J. J. Berzelius said that the salt detonates a little when heated with potassium and is reduced to potassium sulphide and thoria.

Anhydrous thorium sulphate, said J. J. Chydenius, dissolves in cold water

with a hissing noise; and, added J. J. Berzelius, if a large proportion of water is present, the rate of soln. is slow, but if only a small proportion of water is present, the speed is faster and the temp. rises. It seems as if the thorium sulphate dissolves in, say, ten times its weight of water by first forming a hydrate which then passes into soln. P. T. Cleve said that the heat of soln. is positive. P. T. Cleve, L. F. Nilson, G. Wyrouboff, E. Demarçay, and H. W. B. Roozeboom made observations on the solubility, and from the results of the last-named it follows that about 25 parts of the salt can dissolve in 100 parts of water, forming soln. which are metastable between 0° and 100°, and which when kept, spontaneously deposit crystals of the hydrates. According to E. Löwenstein, thorium sulphate forms five hydrates respectively with 9, 8, 6, 4, and 2 mols of water. A trihydrate and a hemienneahydrate have also been reported.

According to J. J. Berzelius, aq. soln. at 10°–15° deposit crystals of **enneahydrated thorium sulphate,** $Th(SO_4)_2.9H_2O$; H. W. B. Roozeboom gave 0°–43° for the range of stability, and H. M. Dawson and P. Williams, 0°–47°. H. W. B. Roozeboom's solubility curves of the different hydrates are shown in Fig. 8. The enneahydrate was obtained by J. J. Berzelius, J. J. Chydenius, and E. H. Kraus, by the spontaneous evap. of acidified soln. of the sulphate—P. T. Cleve used feebly acid soln. J. J. Berzelius found alcohol precipitates the enneahydrate from cold aq. soln., and C. Manuelli and B. Gasparinetti from a strongly acid soln. L. F. Nilson allowed an aq. soln. of thorium sulphate in 50 parts of water to stand in air at 15° until crystals began to separate, and when heated to a rather higher temp., only crystals of the enneahydrate were deposited. G. Wyrouboff said

FIG. 8.—Solubility Curves of Thorium Sulphate.

that the easiest and quickest way of making the enneahydrate is to stir the tetrahydrate with water at 5°–10°—*vide infra*, the solubility of thorium sulphate in acids.

The monoclinic, prismatic crystals of the enneahydrate have been described by J. J. Chydenius, H. Töpsöe, P. T. Cleve, G. Wyrouboff, C. Manuelli and B. Gasparinetti, A. Fock, F. Zambonini, etc. According to E. H. Kraus, the axial ratios are $a : b : c = 0.5972 : 1 : 0.6667$, and $\beta = 98° 17'$. The corrosion figures with water were studied by E. H. Kraus. C. F. Rammelsberg, W. F. Hillebrand and W. H. Melville, and E. H. Kraus discussed the isomorphism of the salt with uranyl sulphate, $(UO_2)SO_4.9H_2O$. H. Töpsöe gave 2·767 for the sp. gr., and E. H. Kraus, 2·766 at 16°. According to P. T. Cleve, and J. J. Chydenius, the crystals effloresce on exposure to air; J. J. Berzelius said that at 15° and less, the crystals are stable in air, but at a higher temp. they lose 60 per cent. of their water, and at 60°, all is lost. M. Delafontaine said that at 100°, 17·01 per cent. of water is given off; while P. T. Cleve said that nearly 7 mols or 21·33 per cent. of water is lost. P. T. Cleve found 7 mols of water evolved over conc. sulphuric acid, and E. Löwenstein noted the amounts of water lost when the enneahydrate is confined in atm. of different humidities corresponding with sulphuric acid of different conc.

Per cent. H_2SO_4 .	30	40	50	60	70	80	90	100
Loss of water . .	0	2·88	3·14	9·31	15·32	15·3	21·57	21·68

J. J. Chydenius said that if not powdered this hydrate dissolves with difficulty in water; and P. T. Cleve said that the unbroken crystals can stay a long time in water without their corners rounding. Observations on the solubility have been made by E. H. Kraus, P. T. Cleve, L. F. Nilson, etc. The following results

are due to H. W. B. Roozeboom, and are expressed in grams of the anhydrous salt per 100 grms. of water :

	0°	10°	20°	30°	40°	51°	55°
Grms. Th(SO$_4$)$_2$ . .	0·74	0·98	1·38	1·995	2·998	5·22	6·76

The results are plotted in Fig. 27. Some observations by E. Demarçay, and G. Wyrouboff are in agreement with these data. H. W. B. Roozeboom observed that crystals of the tetrahydrate appear if the soln. be kept some time at 60°. H. W. B. Roozeboom said that the enneahydrate is stable over the range 0°–43° ; and H. M. Dawson and P. Williams found that densimetric observations gave 47·5° for the transition temp. ; dilatometric measurements gave 46·5° ; and electrical conductivity data, 48°. P. T. Cleve said that the enneahydrate is not soluble in alcohol.

According to P. T. Cleve, the evaporation of a neutral soln. of thorium sulphate, at about 24°, furnishes crystals of **octohydrated thorium sulphate,** Th(SO$_4$)$_2$.8H$_2$O. L. F. Nilson obtained the salt by crystallization from a soln. of the anhydrous salt in 50 parts of water at about 25°—but J. J. Chydenius obtained the tetrahydrate at 25°. G. Wyrouboff also prepared this hydrate. H. W. B. Roozeboom obtained it by allowing a soln. of anhydrous thorium sulphate in 15 parts of water at 0° to stand for some time ; and I. Koppel and H. Holtkamp treated a conc. soln. of thorium nitrate with the calculated quantity of sulphuric acid below 42°—*vide infra*, the solubility of thorium sulphate in acids. The crystals were washed with water and dried in air. P. T. Cleve, and L. F. Nilson have described the crystals. According to G. Wyrouboff the monoclinic, prismatic crystals have the axial ratios $a : b : c = 0·7535 : 1 : 0·5570$, and $\beta = 93°$; and they are feebly doubly refracting. He said that the crystals can be kept for a month in a badly closed vessel without changing the proportion of water ; the loss of water observed by L. F. Nilson is attributed to the presence of some free sulphuric acid. I. Koppel and co-workers gave 22·1–25·13 mm. for the vap. press. of the octohydrate at 30°. P. T. Cleve found that the water is all expelled below a red heat. G. Wyrouboff, and H. W. B. Roozeboom have measured the solubility in water. The latter found for the solubility in grams of the anhydrous salt in 100 grms. of water :

	0°	15°	25°	44°
Grms. of Th(SO$_4$)$_2$ . .	1·0	1·38	1·85	3·71

The results are plotted in Fig. 5. I. Koppel gave 14·944 Cals. for the molar heat of soln. According to H. W. B. Roozeboom, the crystals are relatively stable, and at 42° they pass into the tetrahydrate, and this the more rapidly the higher the temp. Much time is required for the completion of the transformation, even at 60°.

According to H. W. B. Roozeboom, crystals of **hexahydrated thorium sulphate,** Th(SO$_4$)$_2$.6H$_2$O, were produced in a soln. of the octohydrate, acidified with sulphuric acid, after it had stood two years. Although this hydrate is metastable, it hydrates in water very slowly. The solubility expressed in grams of the anhydrous sulphate in 100 grms. of water is approximately (Fig. 5) :

	0°	15°	30°	45°	60°
Grms. Th(SO$_4$)$_2$ . .	1·50	1·63	2·45	3·85	6·64

M. Delafontaine heated a neutral aq. soln. of thorium sulphate on a water-bath, and dried the crystals at 100°. The analysis corresponded with **hemienneahydrated thorium sulphate,** Th(SO$_4$)$_2$.4½H$_2$O. E. Kunheim treated a 60 per cent. soln. of thorium nitrate with sulphuric acid of sp. gr. 1·53, the precipitated crystals were washed with a little water, and dried in air. The analysis also corresponded with the hemienneahydrate. According to M. Delafontaine, the microscopic, needle-like crystals are not hygroscopic. Between 185° and 265°, after nearly 6 hrs., over 6 per cent. of water was lost ; and between 400° and 450°, the crystals lose about 15·68 per cent. of water. E. Kunheim found that the hydrate must be

heated to dull redness before all the water is driven off, and some sulphur trioxide is slowly given off. G. Wyrouboff inferred that in water at 30°–40°, the salt hydrates before it dissolves. At a higher temp., there is evidence of hydrolysis in the acidity of the soln. and the formation of a basic sulphate. The evidence that the hemienneahydrate.is a chemical individual is not above suspicion.

J. J. Berzelius, and J. J. Chydenius obtained **tetrahydrated thorium sulphate,** $Th(SO_4)_2.4H_2O$, by evaporating a neutral or acid soln. of thorium sulphate provided the temp. does not exceed 25°; H. W. B. Roozeboom said the evaporation temp. should be over 43°; and H. M. Dawson and P. Williams, over 47°. The crystals are washed with water, and dried over conc. sulphuric acid. J. J. Berzelius found that alcohol •precipitates the tetrahydrate from hot aq. soln. *Vide infra*—the solubility of thorium sulphate in acids. N. J. Berlin also described the preparation of this hydrate. The product consists of microscopic needles, which, according to W. F. Hillebrand and W. H. Melville, are isomorphous with those of uranium sulphate, $(U(SO_4)_2.4H_2O$. J. J. Chydenius found that the salt loses 6·39 per cent. of water at 100°. J. J. Berzelius, E. Demarçay, and H. W. B. Roozeboom made observations on the solubility of the salt. Expressing the results in grams of anhydrous salt per 100 grms. of water, the last-named found (Fig. 5):

	17°	40°	50°	60°	70°	95°
Grms. Th(SO₄)₂	9·41	4·04	2·54	1·63	1·09	(0·71)

The bracketed result is by E. Demarçay. The solubility curve of the tetrahydrate cuts that of the enneahydrate at 43°. The two hydrates therefore cannot exist at this temp. The transformation of the tetrahydrate into the enneahydrate, however, proceeds very slowly below 43°. H. W. B. Roozeboom said that at 42°, the tetrahydrate passes into the octohydrate. I. Koppel gave 13·523 Cals. for the heat of transformation of the tetrahydrate into the octohydrate; and 28·467 Cals. for the molar heat of soln. of the tetrahydrate. E. Demarçay showed that when the tetrahydrate is boiled with water, the dihydrate, $Th(SO)_2.2H_2O$, and basic sulphate, $ThOSO_4.2H_2O$, are formed. According to I. Koppel and H. Holtkamp, if the octohydrate is boiled with dil. sulphuric acid, the tetrahydrate is formed, and, according to the acidity, the soln. will contain:

Per cent. H₂SO₄	5	10	15
Per cent. Th(SO₄)₂	0·7407	0·4808	0·3882

According to J. J. Chydenius, *trihydrated thorium sulphate*, $Th(SO_4)_2.3H_2O$, is obtained by boiling a feebly acid soln. of thorium sulphate; P. T. Cleve obtained it once. As H. W. B. Roozeboom pointed out, it is very doubtful if this hydrate really exists as a chemical individual.

J. J. Chydenius prepared **dihydrated thorium sulphate,** $Th(SO_4)_2.2H_2O$, by boiling a dil. aq. soln. of thorium sulphate; G. Wyrouboff obtained it by heating one of the other hydrates to 100°, or, according to H. W. B. Roozeboom, at 110°. The last-named found the hydrate dissolves slowly in water at low temp., and the soln. then contains a mixture of the tetra- and ennea-hydrates.

According to E. Demarçay, aq. soln. of thorium sulphate are easily supersaturated. M. Barre found that the lowering of the f.p. of a soln. of 1·5 grms. of the enneahydrate in 100 grms. of water is 0·06°, and the mol. lowering is 23—calculated 22. He also gave for the sp. electrical resistance of aq. soln. with 0·1, 0·01, and 0·001 eq. of the salt per litre, 8·33, 3·16, and 1·26 respectively. J. L. Soret noted that the soln. is fluorescent when exposed in a quartz vessel to the light of the cadmium arc. E. Kunheim studied the action of carbon on thorium sulphate in the electric arc furnace.

O. Hauser and F. Wirth kept an aq. soln. of thorium sulphate for many months in the cold without its becoming turbid, and E. Demarçay said that a cold soln. suffers no perceptible dissociation, but both dil. and conc. soln. are much dissociated when heated. J. J. Berzelius, E. Demarçay, O. Hauser and F. Wirth, and

H. W. B. Roozeboom noted that basic sulphates are obtained from hot aq. soln. M. Barre said that the aq. soln. begins to decompose at about 55°. H. G. Denham showed that aq. soln. are considerably hydrolyzed; the **hydrolysis** of a $\frac{1}{64}N$-soln. amounts to 46 per cent. As indicated above, L. and P. Wöhler and W. Plüddemann obtained no evidence of the formation of basic sulphates during the thermal decomposition of anhydrous thorium sulphate. G. Wyrouboff reported monohydrated **thorium oxysulphate,** $ThOSO_4.H_2O$, to be formed when the hemienneahydrate is heated over 50° in the presence of water; and O. Hauser and F. Wirth obtained the same product by heating a soln. of one part of thorium sulphate in 140 parts of water in a sealed tube for four or five hours at 160°–180°. The product was washed with cold water, and dried over calcium chloride. The needle-like crystals are feebly doubly refracting, and are quite insoluble in water and dil. acids. G. Wyrouboff obtained the *dihydrate*, $ThOSO_4.2H_2O$, by heating hemienneahydrated thorium sulphate with water at 100°. The salt was also made by M. Barre, and O. Hauser and F. Wurth. The percentage solubility is 0·023 at 100°. M. Barre also reported an unstable trihydrate, $ThOSO_4.3H_2O$, to be formed from a soln. of the normal sulphate at 55°. F. Halla made the pentahydrate, $ThOSO_4.5H_2O$, by the action of magnesium carbonate on a mixture of anhydrous thorium sulphate with a little water. The same salt is obtained as a flocculent precipitate on adding magnesium sulphate to a boiling soln. of thorium sulphate or nitrate. The titration with potassium hydroxide soln. using phenolphthalein as indicator proceeds to $ThOSO_4 : KOH = 1 : 1·75$. It is not possible to wash thorium hydroxide free from sulphates by aq. ammonia. Magnesium hydroxide and thorium sulphate, or magnesium sulphate and thorium hydroxide, yield a transparent jelly. O. Hauser and F. Wirth made octohydrated **thorium oxyheptasulphate,** $ThOSO_4.2H_2O.3\{Th(SO_4)_2.2H_2O\}$, or $4ThO_2.7SO_3.8H_2O$, by heating in a sealed tube for 2–3 hrs. between 105°–115°, a mixture of a gram of anhydrous thorium sulphate with 120–150 c.c. of water, filtering and washing with cold water. The product is partly soluble in cold water; and it may be a mixture. There is a clerical error in the analysis. E. Demarçay also made a similar product.

G. Wyrouboff and A. Verneuil reported a number of condensed products which they regarded as **thorium meta-oxysulphates.** They were made by adding dil. sulphuric acid, or a soln. of a normal sulphate—e.g. ammonium sulphate—to a soln. of a condensed chloride or nitrate. The salt $24ThO_2.SO_3.12H_2O$ is obtained from the corresponding chloride; the chloride $Th_8O_7(OH)_{16}Cl_2.2HCl$ furnishes the salt $Th_8O_7(OH)_{16}.H_2SO_4$; which, when washed free from soluble sulphates, gives $Th_8(OH)_{16}SO_4$. The compounds are not stable in water.

If a soln. of thorium sulphate be treated with hydrogen dioxide, P. T. Cleve found that a **thorium peroxysulphate,** $Th_2O_7.SO_3$, is formed. The solubility of thorium sulphate in aq. soln. of hydrochloric acid at 30° has been measured by I. Koppel and H. Holtkamp. Expressing the conc. of the soln. in grams of the anhydrous sulphate per 100 grms. of sat. soln., they found :

Per cent. HCl.	0	4·55	12·14	15·71	18·33	20	23·9
Grms. Th(SO$_4$)$_2$	2·15	3·541	2·811	2·360	2·199	2·110	1·277

$Th(SO_4)_2.8H_2O$ (columns 4·55–18·33) $Th(SO_4)_2.4H_2O$ (columns 20–23·9)

likewise for nitric acid, at 30° :

Per cent. HNO$_3$	0	5·17	16·68	21·99	28·51	33·17	38·82
Grms. Th(SO$_4$)$_2$	2·15	3·68	4·84	4·47	3·88	3·34	2·51

and for sulphuric acid, at 30° :

Per cent. H$_2$SO$_4$	0	0·466	4·97	15·03	32·68	37·80	45·69	74·0	80·5
Grms. Th(SO$_4$)$_2$	2·152	2·055	2·323	1·484	0·3364	0·077	0·0213	0·1208	0

$Th(SO_4)_2.8H_2O$ (columns 0·466–32·68) $Th(SO_4)_2.4H_2O$ (columns 37·80–74·0)

They also made observations at 20°, and at the b.p. of the soln. F. Wirth reported some results at 25° :

N-H_2SO_4	.	.	0	1·1	2·16	4·32	6·68	9·68	10·89	15·15
$Th(SO_4)_2$	.	.	1·593	1·831	1·488	0·8751	0·4312	0·1045	0·0636	0·0308

$$\underbrace{\qquad\qquad\qquad\qquad}_{Th(SO_4)_2.9H_2O}\qquad\underbrace{\qquad\qquad}_{Th(SO_4)_2.8H_2O}\ \underbrace{\quad}_{Th(SO_4)_2.4H_2O}$$

J. J. Berzelius reported an acid sulphate. I. Koppel and H. Holtkamp say that acid sulphates appear as solid phases with soln. of the octohydrated sulphate in 74–80 per cent. sulphuric acid. B. Brauner and J. Picek found that if conc. sulphuric acid be added to a cold sat. soln. of thorium nitrate, and the product heated in vacuo at 130° to remove the excess of sulphuric acid, fine, needle-like crystals are obtained and are very hygroscopic. Analyses correspond with **thorium dihydrotrisulphate,** $Th(HSO_4)_2(SO_4)$. C. Manuelli and B. Gasparinetti obtained white crystals of **thorium dihydropentasulphate,** $Th_2H_2(SO_4)_5.2H_2O$, by fusing 50 grms. of the ash of gas-mantles with 150 grms. of sodium hydrosulphate, and allowing the product to stand in contact with dil. hydrochloric acid. The salt is very soluble in water, and when crystallized from aq. soln., the enneahydrate is formed.

Thorium sulphate forms a series of complex salts with the sulphates of the alkali metals and ammonium. P. T. Cleve [2] mentioned **thorium ammonium tetrasulphate,** $2(NH_4)_2SO_4.Th(SO_4)_2$, as being formed in masses of needle-like crystals by the spontaneous evaporation of a mixed soln. of the component salts. The double salt was said to be very soluble in water, and in a sat. aq. soln. of ammonium sulphate. This salt may be analogous with the dihydrate prepared by A. Rosenheim and co-workers by shaking tetrahydrated thorium sulphate with a conc. soln. of ammonium sulphate, and allowing the filtrate to evaporate over sulphuric acid. M. Barre's solubility curve, Fig. 9, shows the limits of stability
FIG. 9.—The Solubility of Thorium Sulphate in Solutions of Ammonium Sulphate.
FIG. 10.—The Solubility of Thorium Sulphate in Aqueous Solutions of Potassium Sulphate.

of this complex salt. M. Barre measured the solubility of thorium sulphate in aq. soln. of ammonium sulphate at 60°, expressing the conc. in grams of salt in 100 grms. of water, and the composition of the solid phase as $(NH_4)_2SO_4 : Th(SO_4)_2 : H_2O$,

$(NH_4)_2SO_4$	.	.	.	2·13	10·02	16·56	35·20	49·05	52·88	69·74
$Th(SO_4)_2$	.	.	.	3·361	8·947	13·330	9·821	5·750	4·583	1·653
Solid phase	.	.		0 : 1 : 9		1 : 1 : 4		2 : 1 : 2		3 : 1 : 3

The results are plotted in Fig. 10. Consequently with soln. with up to 16·5 per cent. of ammonium sulphate, the solid phase is enneahydrated thorium sulphate; and with 35·2–51·0 per cent. of ammonium sulphate, the solid phase is $(NH_4)_4Th(SO_4)_4.2H_2O$. A. Rosenheim and co-workers obtained tetrahydrated **ammonium thorium trisulphate,** $(NH_4)_2SO_4.Th(SO_4)_2.4H_2O$; and M. Barre showed that the salt is stable in soln. containing 16·5–35·2 per cent.

of ammonium sulphate, Fig. 10.   M. Barre also found that with soln. containing over 51·0 per cent. of ammonium sulphate, as indicated in Fig. 10, the solid phase is trihydrated **ammonium thorium pentasulphate,** $3(NH_4)_2SO_4.Th(SO_4)_2.3H_2O$, which is found in prismatic crystals.   A. Rosenheim and co-workers also reported plates of dihydrated **ammonium thorium hexasulphate,** $4(NH_4)_2SO_4.Th(SO_4)_2.2H_2O$, by allowing a soln. of thorium sulphate with an excess of ammonium sulphate to stand over sulphuric acid.   The salt is very soluble in water.   This salt does not appear on M. Barre's diagram.

P. T. Cleve could not make **lithium thorium sulphate,** but M. Barre showed that the solubility of thorium sulphate steadily increases as the proportion of lithium sulphate in soln. increases; thus, expressing conc. in grams of salt per 100 grms. of water at 25°,

Li_2SO_4 .	.	0	2·57	6·98	11·13	13·18	20·49	25·18
$Th(SO_4)_2$.	.	1·722	4·13	7·95	11·05	12·54	16·92	18·87

Although the solid phase in all cases is thorium sulphate, and the evaporation of the soln. gives crystals of each constituent, he added ; *il semble cependant presque certain qu'il existe en solution un sel complexe provognant cet énorme accroissement de solubilité de 1·722 à 18·87.*   M. Barre found the solubility curve of thorium sulphate with increasing proportions of sodium sulphate has a well-defined maximum ; thus, expressing conc. in grams of salt per 100 grms. of water at 16° :

Na_2SO_4	.	1·094	1·960	2·98	4·11	6·79	9·35	12·24	15·36
$Th(SO_4)_2$	.	1·743	2·387	3·962	3·375	2·136	1·379	1·169	1·048

The solid phase in all cases was hexahydrated **sodium thorium trisulphate,** $Na_2SO_4.Th(SO_4)_2.6H_2O$.   P. T. Cleve also prepared this salt by the spontaneous evaporation of a mixed soln. of the component salts.   The needle-like crystals are very soluble in water.   A. Rosenheim and co-workers also prepared a *dodecahydrate,* $Na_2SO_4.Th(SO_4)_2.12H_2O$, by shaking a conc. soln. of ammonium sulphate with thorium sulphate for a few hours.   Needle-like crystals separate from the filtered soln. after standing some days ; and they are dried in air.   They also made needle-like crystals of the *tetrahydrate,* $Na_2SO_4.Th(SO_4)_2.4H_2O$, by a somewhat analogous process with dil. soln.   The crystals lose their water at 125°.   They failed to make a complex richer in the alkali component.

According to M. Barre, the solubility of thorium sulphate in soln. of potassium sulphate rises rapidly as the conc. of the alkali sulphate increases, and then gradually falls to zero.   Thus, expressing conc. in grams of salt per 100 grms. of water, at 16° :

K_2SO_4 .	.	0	0·424	1·348	1·378	3·092	4·050	4·825
$Th(SO_4)_2$	.	1·390	1·667	1·706	1·637	0·070	0·027	0·003
			0:1:9	1:1:4	2:1:2		7:2:0	

and at 75° :

K_2SO_4 .	.	0	0·865	1·270	1·852	4·659	5·932	9·706
$Th(SO_4)_2$	.	0·9248	1·137	0·907	0·297	0·256	0·123	0·022

The results are plotted in Fig. 10.   The break in the solubility curve corresponds with the formation of definite complex salts.   The lowering of the f.p. ; and the electrical conductivities of the soln. with one per cent. of potassium sulphate correspond with the formation of complex salts.   In 1825, J. J. Berzelius found that if crystals of potassium sulphate be added to a soln. of thorium sulphate, the liquid gradually becomes turbid, and deposits a white, crystalline powder of dihydrated **potassium thorium tetrasulphate,** $2K_2SO_4.Th(SO_4)_2.2H_2O$.   If the soln. of alkali sulphate is neutral and conc., the thorium sulphate is not all precipitated because a film of the double salt protects the alkali sulphate from the soln., but if a boiling sat. soln. of potassium sulphate be added to the soln. of thorium sulphate, as long as a turbidity is produced, all the thorium can be pre-

cipitated even though the soln. contains an excess of acid; the double salt, however, is then contaminated with potassium sulphate. M. Barre's observations show the limits of stability of this salt in aq. soln. J. J. Berzelius made the salt by fusing a mixture of thorium and potassium sulphates at a red heat. He purified the salt and obtained it in " transparent, colourless, rectangular prisms " by recrystallization either by the spontaneous evaporation of the aq. soln., or by cooling the hot aq. soln. According to G. Wyrouboff, the crystals are triclinic pinacoids with axial ratios $a:b:c=0\cdot6029:1:0\cdot5926$; and $\alpha=85°\,0'$; $\beta=95°\,12'$; and $\gamma=85°\,45'$. M. Barre obtained confirmatory results. J. J. Berzelius found that the clear crystals are permanent in air at ordinary temp., but when gently heated, they become turbid and lose their water of crystallization; M. Barre added that the salt is dehydrated below 100°. J. J. Berzelius further noted that the salt dissolves slowly in cold water and abundantly and with ease in hot water; and, unlike the yttrium salt, it is quite insoluble in a sat. soln. of potassium sulphate. The boiling aq. soln. slowly deposits a basic salt, while potassium hydrosulphate remains in soln., but the decomposition reaches a limiting value. The basic salt, unlike the corresponding zirconium salt, is soluble in dil. acids, and it does not dissolve in alcohol. T. Sollmann and E. D. Brown add that it is soluble in tartaric acid soln. J. J. Berzelius observed no signs of combination with fused potassium hydrosulphate. Prismatic crystals of the anhydrous salt $K_4Th(SO_4)_4$ were made by A. Rosenheim and co-workers by shaking a cold soln. of potassium sulphate for many hours with an excess of tetrahydrated thorium sulphate, and allowing the filtered liquid to stand for some hours. M. Barre made acicular crystals of tetrahydrated **potassium thorium trisulphate,** $K_2Th(SO_4)_3.4H_2O$, from soln. of the component salts of the conc. indicated in Fig. 10; he also reported small, probably triclinic, crystals of **potassium thorium henasulphate,** $K_{14}Th_2(SO_4)_{11}$, from soln. of the component salts of the conc. indicated in Fig. 10. They are quite insoluble in soln. of potassium sulphate over 5 per cent. conc. J. J. Chydenius made crystals of dihydrated **potassium thorium hexasulphate,** $K_2Th(SO_4)_6.2H_2O$, by the method for potassium thorium tetrasulphate, but working at 60°–70°.

C. Manuelli and B. Gasparinetti always obtained dihydrated **rubidium thorium trisulphate,** $Rb_2Th(SO_4)_3.2H_2O$, by crystallization from soln. of the component salts no matter what the conc. It is best to work with eq. quantities and the smallest possible amount of water; the soln. should not be boiled; and conc. partly on the water-bath and partly over sulphuric acid. The crystals are sparingly soluble in water, and the aq. soln. crystallizes with difficulty; they prepared dihydrated **cæsium thorium trisulphate,** $Cs_2Th(SO_4)_3.2H_2O$, in a similar manner. V. Cuttica and L. Bonamici found that *thorium and ceric sulphates* have a limited miscibility. L. Fernandes found that when a conc. soln. of thorium sulphate is poured into an excess of a soln. of thallium sulphate, *bellissimi* crystals of **thallous thorium enneasulphate,** $7Tl_2SO_4.2Th(SO_4)_2$, are deposited. If a small proportion of the thallous salt is used, and the soln. evaporated, at a low temp., crystals of tetrahydrated **thallous thorium trisulphate,** $Tl_2SO_4.Th(SO_4)_2.4H_2O$, are formed. The solubility of the former salt expressed in decigrams of thoria, ThO_2, of salt per 100 c.c. of water is:

	0°	20°	40°	60°	70°	80°	90°	100°
ThO_2	2·8	4·15	5·84	6·96	7·14	7·12	6·9	6·3

The maximum in the curve corresponds with the *trihydrate,* $7Tl_2SO_4.2Th(SO_4)_2.3H_2O$. R. F. Weinland and H. Kühl obtained **stannic thorium tetrasulphate,** $ThSn(SO_4)_4.2H_2O$, in fine needle-like crystals, from a mixed soln. of thorium and stannic sulphates. They consider the water to be constitutional:
$$Sn\begin{bmatrix}(SO_4)_2\\(HSO_4)_2\\(OH)_2\end{bmatrix}Th$$

§ 13. Thorium Carbonates

Normal thorium orthocarbonate, $Th(CO_3)_2$, has not been prepared. J. J. Berzelius [1] showed that thorium hydroxide absorbs carbon dioxide from the air, and that alkali carbonates precipitate a basic carbonate from soln. of a thorium salt. According to J. J. Chydenius, the product obtained by passing carbon dioxide through water in which thorium hydroxide is suspended contains 81·48 per cent. of thoria ; and the precipitate obtained by treating a thorium salt soln. with sodium carbonate, not in excess, contains 81·83 per cent. of thoria, and 7·33 per cent. carbon dioxide ; P. T. Cleve obtained respectively 82·8 and 8·68 per cent. According to E. Chauvenet, when thorium dioxide is treated with carbon dioxide at atm. press., the product has the composition $2Th(OH)_4.CO_2$; but if the reaction occurs under a press. of 30–40 atm., dihydrated thorium oxycarbonate or **thorium metacarbonate**, $ThO.CO_3.2H_2O$, is formed. Under similar conditions, thoria, which has been ignited at a temp. not exceeding 430°, furnishes $Th_7O_{13}CO_3$, or $ThOCO_3.6ThO_2$, or **thorium tridecaoxycarbonate.** Octohydrated **thorium oxycarbonate,** $ThOCO_3.8H_2O$, is formed by the action of sodium carbonate on an aq. soln. of a thorium salt ; in vacuo it loses water and forms the dihydrate ; and at 120°, it forms **thorium trioxycarbonate,** $ThO_2CO_3.ThO_2.1\frac{1}{2}H_2O$, or $ThO_3CO_3.1\frac{1}{2}H_2O$.

The precipitates are soluble in an excess of the alkali carbonate owing to the formation of complex salts. This is the basis of a process of separating thoria from the rare earths. When the soln. in alkali carbonate is boiled, it deposits the basic carbonate. T. Sollmann and E. D. Brown observed that the soln. at room temp. gives a precipitate with sodium hydroxide, but not with sodium hydrophosphate, sodium fluoride, or proteids ; they also reported that the basic thorium carbonate precipitated from soln. of thorium salts is soluble in hot soln. of ammonium oxalate ;

insoluble in sodium citrate or tartrate ; soluble in dil. acids, and in tartaric acid. When the soln. of thorium salt is treated with sodium hydrocarbonate, the precipitate may be a *thorium hydrocarbonate ;* it is but sparingly soluble in a hot soln. of ammonium oxalate.

The solubility of thorium hydroxide or basic carbonate in soln. of ammonium carbonate is attributed to the formation of complex salts. A. Rosenheim and co-workers prepared hexahydrated **ammonium thorium carbonate,** $(NH)_2Th(CO_3)_3.6H_2O$, as a microcrystalline powder by saturating with carbon dioxide a soln. of thorium hydroxide and ammonium carbonate, and adding alcohol. According to J. J. Berzelius, thoria does not dissolve in sodium carbonate fused before the blowpipe, and, according to T. Hiortdahl, no carbon dioxide is evolved. P. T. Cleve prepared dodecahydrated **sodium thorium pentacarbonate,** $Na_6Th(CO_3)_5.12H_2O$, by dropping a soln. of thorium chloride or nitrate in an excess of boiling sodium carbonate soln., carbon dioxide is evolved, white flecks appear, and they dissolved on stirring the soln. Alcohol is added and the complex salt precipitated. A. Rosenheim and co-workers prepared prismatic crystals of this salt by warming on a water-bath a soln. of sodium hydrocarbonate in which thorium hydroxide is suspended, and at the same time passing in a current of carbon dioxide. An equal vol. of alcohol was then added to the filtered soln. When kept over sulphuric acid, the *tetrahydrate* is formed, and at 100°, the *dihydrate.* The salt is soluble in cold water but hydrolyzes, so that when warmed thorium hydroxide is precipitated. J. J. Berzelius noted that thorium oxide or carbonate dissolves in a conc. aq. soln. of potassium carbonate. A. Rosenheim and co-workers prepared prismatic crystals of decahydrated **potassium thorium pentacarbonate,** $K_6Th(CO_3)_5.10H_2O$, by the method used for the sodium salt. They also made **thallium thorium carbonate,** $Tl_6Th(CO_3)_5$, as a crystalline precipitate by adding a soln. of thallium salt to a soln. of thorium hydroxide in ammonium carbonate.

§ 14. Thorium Nitrates

As J. J. Berzelius[1] showed, a soln. of thorium nitrate is obtained by dissolving thorium hydroxide in nitric acid, and on evaporating over sulphuric acid, it furnishes six-sided, lamellar crystals of **dodecahydrated thorium nitrate,** $Th(NO_3)_4.12H_2O$. If evaporated under ordinary conditions a thick syrupy liquid is obtained, and finally a clear glass. The salt is very deliquescent, and the aq. soln. does not become turbid when boiled. J. F. Bahr said that when the glassy mass is treated with water, it furnishes clear, tabular and lamellar crystals, and then dissolves completely. I. Koppel and H. Holtkamp made this hydrate by treating a soln. of the commercial salt with ammonia, boiling the liquid for a short time, filtering and washing the precipitate until no sulphates could be detected in the runnings, dissolving the residue in conc. nitric acid, etc. C. R. Böhm, and A. C. Neish also described the purification of thorium nitrate. The commercial nitrate is not a definite hydrate, or even a single compound. It generally contains water eq. to the tetrahydrate, and a little thorium sulphate. The last-named salt imparts to the nitrate qualities which fit the calcined product for incandescent mantles. The detection of impurities in the commercial salt has been described by R. J. Meyer and A. Gumperz, W. Biltz and F. Zimmermann, C. R. Böhm, G. P. Drossbach, etc. When the dodecahydrate is allowed to stand over

conc. sulphuric acid, it loses eight mols of water, and forms the *tetra-hydrate*, $Th(NO_3)_4.4H_2O$. R. Jacoby, and O. Fuhse found that the *hexa-hydrate*, $Th(NO_3)_4.6H_2O$, is obtained by crystallization from hot soln. The tetragonal bipyramidal crystals lose no water when dried over sulphuric acid, and when well dried, the salt is only slightly hygroscopic. B. Brauner obtained the *pentahydrate*, $Th(NO_3)_4.5H_2O$, by heating a mixture of thorium oxalate with nitric acid until a clear soln. is obtained, the greater part of the nitric acid is evaporated off at 80° until crystals begin to form. The acid liquor is then cooled to ordinary temp. H. R. Robinson studied the X-ray spectrum of thorium nitrate.

Thorium nitrate is soluble in water and in alcohol. When heated, it passes into the oxide. R. J. Meyer and A. Anschütz said the decomposition is complete at 500°. I. Koppel and H. Holtkamp gave for the sp. gr. and index of refraction of soln. at 15° containing per 100 c.c.

Grms. ThO_2	0·4	1	2	4	6	8	10	12
Sp. gr. 15°/15°	1·0061	1·0140	1·0327	1·0639	1·0962	1·1297	1·1609	1·1926
Index of refraction	1·33478	1·33582	1·33804	1·34283	1·34724	1·35235	1·35732	1·36188

A. C. Neish and J. W. Burns measured the hydrogen ion conc. of soln. of thorium nitrate. Observations on the radioactive disintegration products have been made by W. Crookes, A. T. Cameron and W. Ramsay, etc. F. Soddy estimated that 350 grms. of thorium nitrate in seven months developed 2×10^{-10} grms. of helium—*vide infra*, radioactivity of thorium. O. Angelucci found that during the electrolysis of a soln. of thorium nitrate, a layer of thorium-A is deposited on the cathode, and thorium hydroxide containing some thorium-X appears on the anode. W. Ramsay and F. L. Usher claimed to have degraded thorium to carbon by the action of radium emanation on a soln. of thorium nitrate. J. O. Perrine observed no sign of the excitation of fluorescence by the X-rays.

R. Jacoby could not prepare an acid salt, *thorium hydronitrate*. B. Szilard studied the peptization of various oxides by soln. of thorium nitrate. H. A. McTaggart found that thorium nitrate in aq. soln., and in conc. as well as in dil. 8×10^{-9} normal soln., gives a positive electric charge to the surface of a sphere of air immersed in it. (In distilled water the charge is always negative.) For conc. in the neighbourhood of 6×10^{-6} normal a sphere initially negative becomes gradually positive as the sphere diminishes in size. G. Wyrouboff and A. Verneuil obtained thorium peroxynitrate by adding a soln. of hydrogen dioxide to a soln. of a thorium salt—*vide* thorium peroxide. According to F. Halla, the titration of thorium nitrate with potassium hydroxide and phenolphthalein is complete when 3·5 mols. KOH are present for 1 atom Th. The addition of ammonium carbonate to a mixed soln. of magnesium chloride and thorium nitrate yields a transparent emulsion, the globules of which change to a hard glass on drying. A. C. Brown studied the adsorption of thorium and uranium-X nitrate soln. by basic ferric acetate; and H. Freundlich and co-workers, by charcoal.

T. Sollmann and E. D. Brown noted that the aq. soln. of thorium nitrate reacts acidic towards blue litmus; and P. T. Cleve, that gelatinous thorium hydroxide is precipitated by an aq. soln. of the nitrate. In aq. soln., therefore, the salt is hydrolyzed: $Th(NO_3)_4 + 4H_2O \rightleftharpoons 4HNO_3 + Th(OH)_4$. G. Krüss and W. Palmaer obtained **thorium oxynitrate** with $Th : NO_3 = 1 : 2$ by dissolving thorium hydroxide in a soln. of thorium nitrate, or by heating a mol of the hydroxide with two mols of nitric acid. R. Jacoby also obtained a similar microcrystalline product by boiling a soln. of thorium nitrate with fuming nitric acid, and cooling the soln. G. Wyrouboff and A. Verneuil made **thorium metanitrate,** $6ThO_2.HNO_3$, and $5ThO_2.2HNO_3$ by the action of nitric acid on the corresponding chloride; and by the action of nitric acid on his polymerized or condensed oxides—*q.v.*

A. Kolb and co-workers prepared a number of complex salts of thorium nitrate with antipyrine, pyridine, quinoline, diethylamine, etc. R. Jacoby prepared plates of pentahydrated **ammonium thorium pentanitrate,** $NH_4Th(NO_3)_5.5H_2O$, by

crystallization from a soln. containing one to two mols of ammonium nitrate per mol of thorium nitrate. It loses three mols of water in a desiccator and forms a white powder of the *dihydrate*. A soln. of one to two mols of ammonium nitrate to one mol of thorium nitrate in nitric acid of sp. gr. 1·25 furnishes crystals of anhydrous **ammonium thorium hexanitrate**, $(NH_4)_2Th(NO_3)_6$, when dried on a porous tile. The crystals do not change in a desiccator. If the soln. contains a large excess of ammonium nitrate, an acid salt, *ammonium thorium hydronitrate*, is formed. R. Jacoby could not make a *lithium thorium nitrate* since the component salts crystallize separately from the aq. soln. of ordinary temp. He could make only one sodium salt, namely, enneahydrated **sodium thorium pentanitrate**, $NaTh(NO_3)_5.9H_2O$, from a soln. of equi-molar parts of sodium and thorium nitrates in dil. nitric acid. The solubility in cold water is less than that of the corresponding potassium salt. When this salt is kept in a desiccator for 14 days, what appears to be the trihydrate is formed. It is not clear if this product is a mixture or a compound.

J. J. Berzelius prepared what now appears to have been enneahydrated **potassium thorium pentanitrate**, $KTh(NO_3)_5.9H_2O$; and R. Jacoby obtained it by evaporating over sulphuric acid and potassium hydroxide, a soln. of equimolar parts of potassium and thorium nitrates in water or dil. nitric acid (1 : 33). The tabular crystals are hygroscopic. By slowly evaporating in an air-bath at 80° a soln. of two mols of potassium nitrate and one mol of thorium nitrate in dil. nitric acid, R. Jacoby obtained prismatic crystals of **potassium thorium hexanitrate**, $K_2Th(NO_3)_6$, which do not change in a desiccator or at 100°, but attract moisture from the air. R. Jacoby prepared isomorphous mixtures of ammonium thorium nitrate and potassium thorium nitrate. If a soln. of three mols of potassium nitrate and one mol of thorium nitrate in nitric acid of sp. gr. 1·25, be evaporated over sulphuric acid and potassium hydroxide, R. Jacoby found that crystals of tetrahydrated **potassium thorium trihydrodecanitrate**, $K_3ThH_3(NO_3)_{10}.4H_2O$, are formed which slowly effloresce in the desiccator. When heated, the salt loses 3 mols of nitric acid and the water. The crystals are deliquescent in air, and are decomposed by water. The salt can be recrystallized from nitric acid of sp. gr. 1·25, and the solubility of the complex is greater than that of the individual salts. R. Jacoby prepared crystals of **rubidium thorium hexanitrate**, $Rb_2Th(NO_3)_6$, from a soln. of a mol of thorium nitrate in one to three mols of rubidium nitrate in nitric acid of sp. gr. 1·25. The solubility in nitric acid is rather greater than that of the ammonium, sodium, or potassium salt. He made **cæsium thorium hexanitrate**, $Cs_2Th(NO_3)_6$, in an analogous manner. V. Cuttica and co-workers found that *ceric and thorium nitrates* are partially miscible. R. Jacoby could not make *thallous thorium nitrate*, since the unchanged salts crystallize separately at ordinary temp., and when the soln. is heated, oxidation to thallic nitrate occurs. He also found that *silver thorium nitrate* could not be obtained because the component salts separate when the soln. is evaporated.

A series of double salts with the general formula $M(NO_3)_2.Th(NO_3)_4.8H_2O$, with M represented by an atom of magnesium, zinc, nickel, cobalt, and manganese, was made by R. J. Meyer and R. Jacoby. By evaporating a soln. of equimolar parts of magnesium and thorium nitrates in a mixture of equal vol. of water and nitric acid of sp. gr. 1·4, over sulphuric acid and potassium hydroxide, the prismatic crystals of octohydrated **magnesium thorium hexanitrate**, $MgTh(NO_3)_6.8H_2O$, which are formed belong to the monoclinic system, and, according to A. Sachs, have the axial ratios $a : b : c = 1·0251 : 1 : 1·5228$, and $\beta = 97° 3·5'$. The double refraction is negative and feeble. R. Jacoby said that the hygroscopic crystals slowly effloresce in a desiccator. They cannot be dehydrated by heat without losing some nitric acid. The corresponding monoclinic crystals of octohydrated **zinc thorium hexanitrate**, $ZnTh(NO_3)_6.8H_2O$, were found by A. Sachs to have the axial ratios $a : b : c = 1·0437 : 1 : -$. They have a feebly negative double refraction.

§ 15. Thorium Phosphates

J. J. Berzelius,[1] P. T. Cleve, and T. Sollmann and E. D. Brown prepared tetra-hydrated **thorium orthophosphate**, $Th_3(PO_4)_4.4H_2O$, as a white gelatinous mass by adding a soln. of sodium hydrophosphate to one of a thorium salt. The product, said J. J. Berzelius, is insoluble in water and in aq. phosphoric acid ; and, according to P. T. Cleve, in acetic and mineral acids. T. Sollmann and E. D. Brown added that it is insoluble in dil. hydrochloric, acetic, citric, and tartaric acids and in soln. of sodium citrate and tartrate. Carbonates, citrates, and oxalates, but not the tartrates, hinder the precipitation of the phosphate. The citrate mixture is again precipitated by boiling, long standing, or adding hydrochloric acid, but not by citric, or tartaric acid, or sodium hydroxide. The salt dissolves in 30 per cent. hydrochloric acid, and the soln. is not precipitated by dilution. The salt is also soluble in a soln. of ammonium citrate. According to A. Colani, if 2–3 grms. of anhydrous thorium metaphosphate, or an alkali phosphate, be heated with 40 grms. of anhydrous thorium chloride, in a tube through which dry carbon dioxide is passed, some of the thorium chloride is volatilized ; and the white crystalline powder which remains after washing with water, is a **thorium chlorophosphate**, $ThCl_4.Th_3(PO_4)_4$, or $ThCl(PO_4)$. It is insoluble in water, and, with the exception of boiling sulphuric acid, it is scarcely attacked by dil. or conc. acids, but it is easily broken down by fused alkali carbonates. The corresponding **thorium bromo-phosphate**, $Th(PO_4)Br$, is obtained in a similar manner. Where the thorium metaphosphate was similarly treated with anhydrous calcium chloride, small, optically inactive crystals of calcium thorium orthophosphate, $CaTh(PO_4)_2$, were formed. With strontium chloride, optically active crystals of **strontium thorium orthophosphate**, $SrTh(PO_4)_2$, were obtained. The corresponding **barium thorium orthophosphate** was an amorphous powder.

K. A. Wallroth made **sodium thorium orthophosphate**, $NaTh_2(PO_4)_3$, by saturating fused microcosmic salt with thoria, and treating the cold mass with hydrochloric acid. L. Troost and L. Ouvrard have stated that normal sodium phosphate does not form a double salt with thorium phosphate. The prismatic crystals are insoluble in all acids. L. Troost and L. Ouvrard made **potassium thorium orthophosphate**, $KTh_2(PO_4)_3$, by melting potassium metaphosphate, KPO_3, and saturating it with thorium oxide, phosphate, or anhydrous chloride. The slowly cooled mass was washed with acidulated water. The microcrystalline

prisms act on polarized light; their sp. gr. is 5·75 at 12°; they are insoluble in hydrochloric or nitric acid, and in aqua regia. If the potassium pyrophosphate be used in place of the metaphosphate in the preceding process, **dipotassium thorium orthophosphate,** $K_2Th(PO_4)_2$, is formed in microcrystalline octahedra. The sp. gr. is 4·688 at 7°; and the salt is insoluble in water but soluble in nitric acid. The corresponding **disodium thorium orthophosphate,** $Na_2Th(PO_4)_2$, was made in a similar manner; the crystals probably belong to the triclinic system. L. Troost and L. Ouvrard reported hexagonal plates of the **potassium thorium phosphate,** $K_{12}Th_3(PO_4)_8$, $6K_2O.3ThO_2.4P_2O_5$, of sp. gr. 3·98 at 12°; and a white powder of $Na_5Th(PO_4)_3$, or $5Na_2O.2ThO_2.3P_2O_5$, of sp. gr. 3·843 at 7°. G. Saring prepared **potassium calcium phosphatothorate,** $Ca_3(PO_4)_2(CaO)_2(K_2O)_2ThO_2$, analogous with the corresponding phosphatosilicate.

P. T. Cleve, and C. Volck made monohydrated **thorium hydrophosphate,** $Th(HPO_4)_2.H_2O$, as a white gelatinous mass, by mixing soln. of orthophosphoric acid, and thorium chloride. The washed precipitate was dried to constant weight at 60°–100°. P. T. Cleve said that the salt loses water when calcined; and C. Volck found it to be soluble in boiling water. P. T. Cleve made **thorium pyrophosphate,** $ThP_2O_7.2H_2O$, by adding a soln. of pyrophosphoric acid to one of thorium chloride; or a soln. of normal sodium pyrophosphate to one of thorium nitrate. The washed precipitate was dried at 100°. It is soluble in soln. of pyrophosphoric acid or sodium pyrophosphate. The last-named soln. is precipitated neither by ammonia nor by oxalic acid. It will be observed that the salt is isomeric with monohydrated thorium hydrophosphate. P. T. Cleve made **sodium thorium pyrophosphate,** $Na_4Th(P_2O_7)_2$, as a white crystalline powder by dissolving thorium pyrophosphate in a boiling sat. soln. of sodium pyrophosphate, and allowing the mixture to stand some days. The soln. is precipitated neither by ammonia nor by oxalic acid.

K. R. Johnsson made **thorium metaphosphate,** $Th(PO_3)_4$, by R. Maddrell's process in which phosphoric acid at a red-heat is treated with thorium sulphate, and heated until the sulphur trioxide is expelled. The excess of phosphoric acid is removed by decantation with water. L. Troost and L. Ouvrard also made it by the action of an excess of metaphosphoric acid on anhydrous thorium chloride or bromide; and they gave 4·08 for the sp. gr. of the rhombic plates at 16·4°; K. R. Johnsson gave 3·922 for the sp. gr. of the microscopic plates. A. Colani found the salt to be isomorphous with uranium metaphosphate, $U(PO_3)_4$, with which it forms mixed crystals. L. Troost and L. Ouvrard said that the salt is insoluble in water; they also made **sodium thorium metaphosphate** in triclinic prisms of sp. gr. 5·62 at 16°; the crystals act on polarized light; and are soluble in nitric and hydrochloric acid.

The Lindsay Light Co. prepared **thorium sulphatometaphosphate,** $Th(PO_3)_2SO_4$, in the form of white, acicular crystals, by dissolving 120 grms. of octohydrated thorium sulphate, in 50 c.c. of 80 per cent. phosphoric acid, and heating for 10 hrs. at 280°. Water and sulphuric acid fumes are evolved and the product forms a nearly solid, crystalline mass, insoluble in water or dil. acids. The same substance is also obtained by heating thorium phosphate with an equal weight of sulphuric acid, preferably in presence of 20–40 per cent. of phosphoric acid, for 10 hrs. at a temp. above 260°.

CHAPTER XLV

GERMANIUM

§ 1. The Discovery and Occurrence of Germanium

K. G. A. VON WEISSENBACH,[1] and A. Breithaupt described a mineral, obtained from St. Michaelis, near Freiberg (Saxony), which was called *Plusinglanz*—from πλούσιος, rich—in allusion to the lustre. An earth from Himmelsfürst in the same district was described by E. W. Neubert, and A. Weisbach, and named **argyrodite**—from ἀργυρώδης, argentiferous—in allusion to its composition. A. Weisbach reported an analysis indicating the presence of a small proportion of mercury. C. Winkler obtained 74·72 per cent. Ag; 17·13, S; 0·66, FeO; 0·22, ZnO; and 0·31, Hg. The result was about 7 per cent. too low. He attributed the deficiency to the presence of an unknown element, precipitated as sulphide in the hydrogen sulphide group, and *dem Antimon in mancher Beziehung ähnlichen*, but yet quite different. The new element was called **germanium** from the Latin name *Germania*.

On account of the likeness of argyrodite to antimony glance (stibnite), C. Winkler at first assumed the new element must be D. I. Mendeléeff's unknown eka-antimony, occupying a place between antimony and bismuth in the periodic table. When C. Winkler had worked over the properties of germanium it was found that it did not fit well into the places assigned in the periodic table to eka-antimony and eka-cadmium, but it did fit well into the place reserved for eka-silicon. This is illustrated by Table IV, 1. 6, 4. G. A. Quesneville proposed to use D. I. Mendeléeff's term eka-silicon in place of germanium, but this was not adopted.

The analyses of C. Winkler, S. L. Penfield, V. M. Goldschmidt, F. Kolbeck, A. Frenzel, and G. T. Prior and L. J. Spencer show that different samples of argyrodite contain from 4·99 to 7·05 per cent. of germanium; and that the mineral is best regarded as $4Ag_2S.GeS_2$—C. Winkler first gave $3Ag_2S.GeS_2$—*i.e. silver sulphogermanate*, Ag_8GeS_6. T. Kolbeck, and A. Frenzel showed that the mineral *Plusinglanz* is a variety of argyrodite. A. Weisbach first described argyrodite as belonging to the monoclinic system. S. L. Penfield obtained a similar mineral from Potosi, Bolivia, but furnishing cubic crystals, thence he inferred that argyrodite is dimorphous, and he assigned the name canfieldite—after F. A. Canfield—to the cubic form. A. Weisbach subsequently showed that the mineral from Freiberg is cubic, and tetrahedral. S. L. Penfield described a mineral from La Paz, Bolivia, which was previously thought to be argyrodite, but which was shown to be a kind of stanniferous argyrodite with Ge : Sn=5 : 12, and he transferred the name canfieldite from the Bolivian argyrodite to the isomorphous stanniferous form. As emphasized by A. W. Stelzner, tin and germanium belong to the same chemical group, and are isomorphous with one another, and that silver sulphostannate isomorphous with argyrodite is to be anticipated. Canfieldite, said S. L. Penfield, may therefore be regarded as *silver sulphostannate*, Ag_8SnS_6, which occurs in Bolivia admixed with the isomorphous sulphogermanate, furnishing $Ag_8(Ge,Sn)S_6$. The Bolivian mineral has about 1·83 per cent. Ge, and 6–10 per cent. Sn. The deposits of argyrodite have been described by A. W. Stelzner, A. Frenzel, R. Peele, and

H. Reck. V. M. Goldschmidt emphasized the analogy between the formula of fahlerz, $3R_2S.R'_2R''S$, of sp. gr. 4·921, and mol. vol. 165, and argyrodite $3R_2S.R'_2R''S$, of sp. gr. 6·266 and mol. vol. 180. The sp. gr. is 6·1–6·3 ; and the hardness 2–3. J. L. C. Schröder van der Kalk discussed the colour of argyrodite ; and A. de Gramont, the spark spectrum. G. T. Prior and L. J. Spencer showed that A. Damour's *brongniardite* is nothing but a variety of argentiferous argyrodite. The dark reddish-grey mineral *germanite* obtained by O. Pufahl from Tsumeb, S.W. Africa, has a composition approximating $Cu_5(Cu,Fe)_6AsGeS_{12}$. Analyses were reported by H. Schneiderhöhn, F. W. Kriesel, W. Keil, and E. Thomson. The latter represented it by the formula $10Cu_2S.4GeS_2.As_2S_3$. J. Lunt made a spectroscopic analysis of germanite. The black mineral, *ultrabasite*, reported by V. Rosicky and J. Sterba-Böhm from the Himmelsfürst mine, Freiberg, has the composition of a *silver germanium lead sulphantimonite*, $11Ag_2S.28PbS.3GeS_2.2Sb_2S_3$, and P. Groth and K. Mieleitner suggest that it is a mixture of lead germanium sulphide, $3GePb_2S_4$, with $2Pb_3(SbS_3)_2$, $16PbS$, and $11Ag_2S$. The axial ratios of the rhombic or pseudo-tetragonal crystals are $a : b : c = 0·988 : 1 : 0·462$, when those of teatlite are $a : b : c = 0·93 : 1 : 1·31$. The hardness of ultrabasite is 5, and sp. gr. 6·026. It decrepitates and decomposes when heated ; and is slowly attacked by hydrochloric and nitric acids.

Germanium is a scarce element. J. H. L. Vogt[2] estimated that the igneous rocks in the earth's crust contain $n \times 10^{-12}$ per cent. of this element ; and F. W. Clarke and H. S. Washington made a similar estimate. According to H. A. Rowland, lines in the solar spectrum correspond with those of germanium, and indicate the presence of that element in the sun. C. Winkler[3] said that germanium although sparse may be really more widely distributed than it is at present assumed to be because, owing to the want of a delicate and sharp distinguishing test, its presence may easily be overlooked. G. Urbain examined the ultra-violet spectrum of 64 samples of *zinc blende*, and he found germanium to be present in 38 samples, and appreciable quantities were found in five samples from Webb City, Missouri ; Stolberg, Aix-la-Chapelle ; Turkey in Europe ; Raible, Corinth ; and Mexico. A. del Campo y Cerdan also examined 68 zinc blendes and found germanium to be present in 50 of the samples—*vide* indium, 5. 35,1. G. H. Buchanan also found germanium present in many zinc blendes, and J. H. Müller, in the smithsonite ore of Kentucky, and in the mine-water and ore washings. W. F. Hillebrand and J. A. Scheerer found it in zinc blendes and carbonate ores from Missouri, Idaho, Colorado, Nevada, and Utah.

The mineral *franckeite*, $5PbS.Sb_2S_5.2SnS_2$, described by A. Stelzner was found to contain about 0·10 per cent. of germanium. G. Krüss found up to about 0·1 per cent. of germanium in euxenite ; K. von Chrustschoff, in harmony with D. I. Mendeléeff's suggestion, found this element to be present in many tantalum and columbium minerals ; up to 1·5 per cent. in *samarskite ;* 0·01 per cent. in *tantalite ;* 0·03 per cent. in *columbite* and *fergusonite ;* and traces in *gadolinite*. G. Krüss and L. F. Nilson reported germanium in fergusonite from Arendal. G. Lincio failed to find any trace of germanium in samarskite ; and L. M. Dennis and J. Papish found none in American samarskite, and they suggested that K. von Chrustschoff's methods were unsatisfactory. A. Hadding found germanium in *cassiterite* from Finbo, and Mamacka, but none in cassiterite from Finland, and Bohemia. G. Neumann also reported germanium to be present in tin compounds. G. H. Buchanan found up to about 0·25 per cent. of germanium in *zinc oxide*, and *spelter* prepared from Missouri and Wisconsin zinc blendes. C. Winkler found no germanium in the flue-dust from the roasting chambers of the ores from the Freiberg mine where argyrodite occurs. J. Bardet reported germanium to be present in the mineral waters of Vichy to the extent of one part in 40,000,000 parts of water. E. Cornec detected traces of germanium in the ashes of the marine plant *Laminaria*.

§ 2. The Extraction and Preparation of Germanium

The chief associates of germanium are silver, copper, zinc, cadmium, gallium, indium, titanium, tin, lead, arsenic, antimony, tantalum, and columbium. Germanium sulphide is precipitated by hydrogen sulphide from highly acidified soln., and the sulphide is readily soluble in ammonium sulphide; consequently, germanium is easily separated from the majority of its associates. The main difficulty is the removal of arsenic and tin—which occur in the same analytical group— *vide infra*, reactions of analytical interest.

C. Winkler [1] extracted germanium from argyrodite by heating a mixture of the finely powdered mineral with sodium carbonate and sulphur at a moderate red heat. The product was extracted with water, and the soln. treated with the exact amount of sulphuric acid necessary to decompose the whole of the sodium sulphide present. After being left for a day, the soln. was separated from the precipitate consisting of sulphur, and arsenic and antimony sulphides, and treated with hydrochloric acid so long as a precipitate was formed. The whole was then sat. with hydrogen sulphide, filtered, and the white voluminous precipitate of germanium sulphide washed with 90 per cent. alcohol sat. with hydrogen sulphide. The sulphide was roasted at a low temp. warmed with conc. nitric acid, and the oxide so obtained ignited.

G. Krüss fused euxenite with potassium hydrosulphate and heated the product with hydrogen chloride to remove the iron. The washed product was treated with

ammonium sulphide at 100° for 8 days. The germanium was separated from the soln. by C. Winkler's process just described. G. Urbain and co-workers treated the acid soln. of Mexican zinc blende with hydrogen sulphide. The mixed precipitate of the sulphides of arsenic, molybdenum, and germanium was dissolved in the minimum amount of ammonia and the soln. fractionally precipitated by diminishing concentration. In this way, the germanium was left alone in soln. 550 grms. of the blende yielded 5 grms. of purified germanium.

G. H. Buchanan based a process for separating the element from germaniferous zinc oxide on the volatility of germanium tetrachloride. A mixture of the crude oxide and conc. hydrochloric acid was heated in a distilling flask and the distillate treated with hydrogen sulphide. The germanium sulphide so obtained would be contaminated with arsenic. L. M. Dennis and co-workers prevented the arsenic volatilizing as trichloride along with the germanium tetrachloride by passing a current of chlorine through the apparatus during the distillation. This maintained the arsenic in the quinquevalent form which does not volatilize with the germanium tetrachloride. J. H. Müller was unable to obtain germanium tetrachloride free from arsenic by the distillation of the hydrochloric acid soln. in a current of chlorine ; but L. M. Dennis and co-workers found that if the distilling flask be fitted with a fractionating column, the arsenic trichloride, boiling at 129°, and germanium tetrachloride, boiling at 86°, can be adequately separated, and a distillate free from arsenic obtained. H. C. Fogg and C. James described the extraction of germanium from zinc oxide. J. S. Thomas and W. Pugh extracted germanium from germanite, reducing the dioxide by fusion with potassium cyanide and carbon. W. Keil digested the powdered mineral with a hot mixture of nitric and sulphuric acids, until white fumes of sulphuric acid were given off, and cooled the mass. The product was suspended in hydrochloric acid, and distilled in a current of chlorine. Germanium tetrachloride collected below the hydrochloric acid in the receiver. The two liquids were separated, and the free chlorine removed by shaking with mercury. The tetrachloride was then distilled and converted into sulphide or oxide as required.

C. Winkler found that small quantities of germanium oxide or sulphide can be reduced by heating in a current of hydrogen. The operation is *lästig*. The metal is also precipitated as a brown or grey powder from soln. of its salts. Powdered germanium is also obtained by heating a mixture of potassium fluogermanate and sodium, but it is difficult to separate the powdered metal from the sodium fluoride. C. Winkler found the most convenient method of preparation is to mould little balls from a mixture of the powdered oxide with 15–20 per cent. of starch and a little boiling water. These were dried and carbonized at a dull red heat ; and introduced into a crucible between layers of charcoal. A porous regulus of germanium was obtained by heating the crucible and contents at bright redness for an hour. The regulus was then fused under borax glass, and germanium was obtained as a metallic bead. A little germanium oxide dissolves in the borax. L. M. Dennis and co-workers obtained a poor yield by reducing the dioxide with aluminium ; and they used C. Winkler's method fusing the powdered metal below molten sodium chloride in place of borax.

The lode of argyrodite at Freiburg is virtually exhausted ; germanite has not been worked. Another possible source of germanium is in the mineral water of Vichy. The evaporation of a quarter million litres furnishes a residue containing about 0·06 grm. of germanium oxide per 100 kgrms. of residue. Hence, the water has the equivalent of about 0·00024 mgrm. per litre.

§ 3. The Properties of Germanium

According to C. Winkler,[1] germanium is a greyish-white metal which has a conchoidal fracture and a crystalline structure. The **crystals** are octahedral. According to L. M. Dennis and co-workers, the slow cooling of the metal fused under sodium chloride gave a button whose upper surface had a fine crystalline structure. The metal is an aggregate of elongated crystals bounded in some cases by octahedral faces. Some of the crystals are nitched, or covered with dendritic branches. **X-radiograms** by A. W. Hull, R. N. Pease, and N. H. Kolkmeijer and co-workers show that the crystals are cubic, and the space-lattice has the same arrange-ment as the diamond with the edge of unit cube 5·61 to 5·63 A. M. L. Huggins deduced an **electronic structure** of the metal. C. Winkler gave 5·469 for the **specific gravity,** at 20·4°. L. M. Dennis and co-workers found the sp. gr. 5·35 at 20°/20°, and A. W. Hull and co-workers calculated 5·36. M. L. Huggins calculated the **atomic radius** to be 1·22 A. J. J. van Laar calculated the value of b of J. D. van der Waals' equation, $b=0·00210$; and for a, $\sqrt{a}=0·07$; and for the valency attraction A, $\sqrt{A}=36$. L. M. Dennis and co-workers found that ger-manium is so brittle, that it cannot be drilled, and that Brinell's hardness test could not be applied owing to the shattering of the blocks. The metal scratches adularia, but not epidote, so that its **hardness** on Moh's scale is 6·25. Cast ger-manium was found by P. W. Bridgman to have a **compressibility** of $\kappa=1·378\times10^{-6}$ at 30° ; and the proportional change of compressibility with press. $d\kappa/dp =0·98\times10^{-5}$, where $d\kappa/dp=2b$, and $\kappa=a$ of the formula $\delta v=v(-ap+bp^2)$ for the change of volume when the press., p, is expressed in kgrms. per sq. cm. The **melting point** is near 900°. The beads of metal unite into one globule only when fused under borax ; potassium cyanide or sodium carbonate give too great a loss by scorification. W. Biltz found that the metal melts at 958°±5° in an atm. of hydrogen ; and if sat. with oxide, at 916°±5°. W. R. Mott gave 958° for the m.p. ; and L. M. Dennis and co-workers made observations on the sprouting of the metal which has been melted and quickly cooled. The phenomenon is ascribed to the great increase in vol. which occurs when the molten metal solidifies. L. M. Dennis and co-workers showed that the effect is not due to the absorption of gas by the liquid and its expulsion on solidification as in the spitting of silver. The metal does not volatilize appreciably at its m.p., and at 1350°, V. Meyer found it to be

slightly volatile, but even at 1500°, L. F. Nilson and O. Pettersson found that the **volatility** is too low for measuring its vap. press., or determining its vap. density. C. Winkler attributed the white cloud rising from a crucible in which germanium was melted under borax to " the vaporization temp. being only slightly above its m.p." W. Biltz showed that the cloud is due to the volatilization of germanous oxide, not the metal ; and L. M. Dennis and co-workers showed that the metal alone is not volatile at a temp. 300° above its m.p. W. Biltz said that the metal is not appreci-ably volatile in nitrogen at 1250°, but in the presence of some oxide, vapour is observed from 750° upwards.

Fig. 1.—Heating and Cooling Curves of Germanium.

When germanium is heated below its m.p., there is evidence of inversion points at 117° and 560°; Fig. 1, which L. M. Dennis and co-workers take to show that the solid passes through at least two modifications—

vide infra, electrical properties. According to the calculations of W. R. Mott, the b.p. of germanium is 1900° at atm. press. ; J. J. van Laar gave 2610° ; and for the **critical temperature,** 4170°, and the **critical pressure,** 910 atm. L. F. Nilson and O. Pettersson found the **specific heat** between 0° and 100° to be 0·0737 ; between 0° and 300°, 0·0768 ; between 0° and 400°, 0·0757, thus making the **atomic heat** 5·34, 5·57, and 5·49 respectively.

Germanium compounds do not colour the bunsen flame, but the **spark spectrum** of germanium has a number of bright lines particularly in the blue and violet. This was investigated by C. Winkler, A. de Gramont, J. Lunt, and F. Exner and E. Haschek. The most intense lines are 2592·65, 2651·29, 2651·69, 2709·69, 2754·68, 3039·20, 4179·20, and 4226·76. The **arc spectrum** was examined by H. A. Rowland and R. Tatnall, J. Papish, and F. Exner and E. Haschek. The most intense lines are 2592·64, 2651·28, 2651·69, 2691·45, 2709·70, 2754·69, 3039·22, and 3269·62. J. Papish considers the blue line of wave-length 468·1 in the spark spectrum is most suitable for the identification of germanium. W. J. Humphreys measured the effect of press. ; L. de Boisbaudran calculated the at. wt. from the spectral lines ; W. N. Hartley and H. Ramage examined the banded flame spectrum. E. Paulson found three triplets in the line spectrum of germanium. Germanium salts give no absorption spectrum, and J. Formánek found the salts do not react with alkanna tincture. H. J. C. Ireton measured the ultra-violet spectrum from 213·8 A to 319·7 A. In the **X-ray spectrum,** W. Duane and co-workers, B. Walter, A. Leide, and M. Siegbahn gave for the K-series in Angström units, or 10^{-8} cm. units, $a_2a=1\cdot261$; $a_1a=1\cdot257$; $\beta_1\beta=1\cdot131$; and $\beta_2\gamma=1\cdot121$; and E. Hjalmar gave for the L-series, $a_1a=10\cdot4136$.

C. Benedicks found the **electrical resistance** of germanium is between that of silicon and that of tin. C. C. Bidwell measured the electrical resistance of germanium at different temp., and the results are shown by the continuous curve, Fig. 2.

There are well-defined minima at −116° and 645°. From −188° to 100°, the resistance follows the exponential law, $R=A(1+a\theta+\beta\theta^2)e^{Q/kT}$, where A, a, β, Q, and k are constants. This equation requires a minimum at −116°, and a change in the temp. coeff. from positive to negative. Above 600°, the law applies but with different constants. In the intermediate region, the law is obscured by an allotropic transformation. Carbon seems to have a minimum at some high temp. According to J. Königsberger, and K. Schilling, silicon, titanium, and zirconium seem to

FIG. 2.—The Resistance and Thermoelectric power (Pt-Ge) of Germanium at Different Temperatures.

follow a similar law ; silicon has a negative temp. coeff. and a minimum obscured by transformation at a lower temp. than carbon ; titanium has a minimum at about 100° ; zirconium has an inflexion at a lower temp. ; and H. K. Onnes and G. Holst found that tin approaches a minimum at a still lower temp. The **thermoelectric power** of the Ge-Pt couple is shown by the dotted line, Fig. 2. The curve is straight from about −183° to 125°, and again straight from 450° to 700° ; between these temp. there is a slow reversible transformation beginning at about 125° and reaching completion at about 450°. Up to 300° the thermoelectric current is positive with reference to platinum ; it becomes zero at 300°, and is negative beyond that temp. The positive sign means that the current flows across the hot junction from platinum to germanium ; or in the external circuit the direction of flow is from the germanium to the platinum. C. Benedicks found the thermoelectric force of the Cu-Ge couple to be extraordinarily high being −380 microvolts per degree. This is surpassed by only one other element, silicon. E. Merritt showed that the contact rectification of germanium is less than that of

silicon. The relation of the **diamagnetic** properties of germanium to the electronic structure of the atom has been studied by B. Cabrera, and A. Dauvillier.

The gas developed by the action of germanium on molten potassium hydroxide is not germanium hydride, but, as C. Winkler showed, it is nothing but hydrogen. Germanium and **hydrogen** are not known to unite directly. J. H. Müller said that there is a loss by heating the metal over 700° in hydrogen owing to the formation of a volatile hydride, but L. M. Dennis showed that there is no loss below 800°, and the molten metal does lose in weight when heated in hydrogen. J. H. Müller and N. H. Smith's observation was attributed to the contamination of the metal by chloride which is reduced by hydrogen to volatile germanous chloride—*vide infra*. D. I. Mendeléeff's eka-silicon should have properties between those of silicon and tin, and germanium has these qualifications. According to C. Winkler, fused and crystallized germanium does not oxidize at ordinary temp. either in dry or in moist **air ;** and it does not lose its lustre. Pieces of germanium may be heated nearly to redness without change, but at an incipient red heat, the metal becomes covered with a thin film of oxide. The pulverulent metal which has not been melted is much more readily oxidized. The metal burns with incandescence when heated in **oxygen.** L. M. Dennis and co-workers found that oxidation does not begin appreciably at 600° during 30 hrs., but at 605°, oxidation occurs and proceeds rapidly at 615° but is not completed at 900°. It is not possible to oxidize germanium below 730°, and at higher temp. there is a loss by the volatilization of germanous oxide, which is then further oxidized. No appreciable effect occurs when germanium is kept at room temp., or at 90° in contact with **water ;** but at room temp., a 3 per cent. soln. of **hydrogen dioxide** forms some dioxide which dissolves in the liquid ; the action is fast at 90°, and faster still at 100°. When a drop of the fused metal is allowed to fall on paper, it divides itself into several globules which move continually over the surface of the paper, forming black tracks. Germanium which has been fused preserves its lustre at ordinary temp. in **chlorine,** but when heated, it burns with a bluish-white flame, forming germanium tetrachloride ; pulverulent germanium inflames spontaneously in chlorine at ordinary temp. When heated in **bromine** vap., the metal burns with a yellowish flame, forming germanium tetrabromide. When germanium is heated in **iodine** vap. to incipient redness, an iodide is formed. Germanium is not attacked by **hydrofluoric acid** at ordinary temp. ; L. M. Dennis and co-workers observed only a loss of 0·1 per cent. in $19N$-HF at room temp., and at 90°, a loss of 0·7 per cent. C. Winkler showed that **hydrochloric acid** has very little action ; and L. M. Dennis observed no appreciable change in hydrochloric acid conc. or diluted (1 : 1) at room temp. or at 90°. According to C. Winkler, when germanium is heated in a stream of **hydrogen chloride,** hydrogen is liberated and germanium chloroform, $GeHCl_3$, is produced : $Ge+3HCl=H_2+GeHCl_3$. C. Willgerodt did not observe any signs of its accelerating the chlorination of organic products, catalytically. According to C. Winkler, when germanium is heated with **sulphur** to incipient redness, germanous sulphide is formed. L. M. Dennis and co-workers observed no attack by **hydrogen sulphide** below 200°, and the attack is comparatively slight until the dissociation of the gas begins (400°–440°), when a reaction occurs between the germanium and the sulphur. They also found that **sulphur dioxide** acts on crystalline germanium somewhat below 500°, and the reaction is rapid between 510° and 530°—germanium disulphide and dioxide are formed. According to C. Winkler, when germanium is heated with conc. **sulphuric acid,** sulphur dioxide is given off, and a white sulphate is formed which is soluble in water. L. M. Dennis and co-workers observed no change in the metal kept at room temp., or at 90° in 1 : 1 sulphuric acid ; with conc. sulphuric acid at room temp. there was no appreciable action, but at 90° there was a loss of 1 per cent. in about a week. According to C. Winkler, the action of powdered germanium on **nitric acid** is very violent at first; nitric oxide and germanium dioxide are formed. According to L. M. Dennis and co-workers, 1 : 1 nitric acid acted on the metal superficially at room temp. with a loss of 7 per cent., and at 90° with a loss

of 1 per cent. Conc. nitric acid at room temp. darkened the surface of the metal, but there was no appreciable loss in weight. According to C. Winkler, the metal readily dissolves in **aqua regia.** When melted under borax, germanous oxide, GeO, is formed. A conc. soln. of **potassium hydroxide** has no action; but when powdered germanium is projected on the fused alkali, there is a violent reaction, hydrogen is set free, and potassium germanate is formed. L. M. Dennis and co-workers found that a 50 per cent. soln. of sodium hydroxide had no appreciable action during a week's exposure at room temp. and at 90°; but with a 10 per cent. soln., there was a slight action, and a loss of about 0·5 per cent. The metal dissolves quickly in fused sodium and potassium hydroxides, and the cold mass dissolves in water giving a clear, colourless soln. The metal is attacked and dissolved by fused **sodium carbonate ;** and it is slowly attacked by fused **potassium hydrosulphate.** The reaction with fused **sodium dioxide** is vigorous, and the metal is dissolved. Fused **sodium chloride** has no action, but there is a slight reduction of fused **sodium sulphate.** Molten **potassium cyanide** had no appreciable action. According to C. Winkler, fused borax dissolves a little germanium. Mixtures of germanium with **potassium nitrate** or **potassium chlorate** detonate when heated; L. M. Dennis found that fused potassium chlorate slowly attacks and dissolves germanium; and that fused potassium nitrate is immediately reduced, gas is evolved, and some of the metal is oxidized and dissolved. C. Winkler found that when heated with **mercuric chloride** or **bromide,** germanium chloride or bromide is formed. Molten germanium does not attack **porcelain,** but it alloys with **platinum,** forming a brittle, fusible alloy.

Reactions of analytical interest.—Germanium salt soln. give no precipitate with **hydrochloric acid ;** but when the acid soln. is treated with **hydrogen sulphide,** white germanium sulphide, GeS_2, is precipitated; the precipitation is complete only in the presence of a large excess of conc. acid. Germanium sulphide is either soluble in or peptized by water and by aq. soln. of hydrogen sulphide; it must therefore be washed with dil. hydrochloric or sulphuric acid sat. with hydrogen sulphide, then with alcohol sat. with the same gas, and finally with ether. The precipitate is readily soluble in a soln. of ammonium sulphide, forming a stable sulphosalt. The addition of an excess of acid precipitates the sulphide unchanged. If the germanium sulphide is mixed with antimony and tin sulphides, the germanium sulphide alone dissolves when the mixture is treated with a soln. of ammonium carbonate. Arsenic sulphide, if present, can be separated by fractional distillation from a hydrochloric acid soln. in a stream of chlorine. The germanium tetra-chloride is the most volatile. The chlorine keeps the arsenic in the quinquevalent state; potassium chlorate, permanganate, or chromate act similarly. This subject has been discussed by G. H. Buchanan,[2] L. M. Dennis and co-workers, and P. E. Browning and S. E. Scott. K. Haushofer tested minerals for germanium by heating the powder in hydrogen sulphide and examining the sublimate of germanium sulphide, which, when warmed with nitric acid, forms white germanium dioxide soluble in water and dil. nitric acid. Soln. of germanium tetrachloride give no precipitate with **alkali hydroxide** because the hydrated germanium dioxide becomes colloidal, and an excess of alkali forms a soluble germanate. Soln. of **ammonia,** or **ammonium or sodium carbonate,** partially precipitate the hydrated dioxide. O. Brunck found **sodium hyposulphite** gives no precipitate with neutral or acid soln. of germanium salts. Brown, pulverulent germanium is slowly deposited when **zinc** is placed in a soln. of a germanium salt. The analysis of germanium ores was described by S. L. Penfield, G. T. Prior and L. J. Spencer, and V. M. Gold-schmidt. In quantitative work, L. M. Dennis and E. B. Johnson recommended precipitating the germanium as the disulphide, oxidizing the sulphide with 3 per cent. hydrogen dioxide, and finally weighing it as germanium dioxide.

The atomic weight of germanium.—Germanium forms two series of compounds in which the element is respectively bivalent and quadrivalent. The latter compounds are the more stable. The quadrivalency of the element with a hydrogen

eq. of 18 is in agreement with Avogadro's hypothesis applied to the vap. densities of the volatile tetrachloride and bromide ; it is also in agreement with the sp. ht. rule ; with the law of isomorphism applied to the fluosilicates and fluogermanates ; and with the periodic law as indicated. C. Winkler [3] decomposed the tetrachloride by sodium carbonate ; added a known excess of standard silver soln., and titrated back with ammonium thiocyanate. He thus obtained for the ratio Ag : GeCl$_4$, 0·201512 : 1. This agrees with the at. wt. 72·3. G. P. Baxter and W. C. Cooper analyzed the tetrachloride and obtained 72·6 for the at. wt. of germanium; and with the tetrabromide, 72·599–72·609. J. H. Müller computed 72·41–72·45 from the ratio K$_2$GeF$_6$: 2KCl. Using different standards, F. W. Clarke calculated 72·504; and B. Brauner, 72·41. The International Table gives 72·5 for the best representative value. The **atomic number** of germanium is 32. F. W. Aston found indications of three **isotopes** of germanium with at. wts. 70, 72, and 74 respectively, and in agreement with the average at. wt. 72·5. The Ge$_{70}$ isotope is isobaric with the weakest and heaviest component of zinc, and Ge$_{74}$ is isobaric with the weakest and lightest isotope of selenium. The **electronic structure** of the atom was discussed by N. V. Sidgwick, and H. G. Grimm and A. Sommerfeld.

§ 4. Germanium Hydrides

As indicated above, hydrogen and germanium do not unite directly. E. Voegelen [1] obtained **germanium tetrahydride,** or **monogermane** or **germano-methane,** GeH_4, by an indirect process. If germanium chloride is reduced with sodium amalgam, the hydrogen evolved, even when bubbled through sodium hydroxide soln., burns with a bluish-red flame, and deposits a mirror on a cold porcelain surface. Germanium hydride, to which this phenomenon is attributed, may be prepared like antimony and arsenic hydrides, in testing for these substances ; the mirror obtained by heating the tube through which the issuing gas passes is red in transmitted, green in reflected, light ; it is soluble in sodium hypochlorite, difficultly so in hot hydrochloric acid ; heating in air or with conc. nitric acid changes the mirror into white germanic oxide, which, when acted on with hydrogen sulphide in hydrochloric acid soln., gives a white precipitate of germanium sulphide soluble in ammonium sulphide. When germanium hydride is passed through silver nitrate soln., a black compound of germanium and silver is precipitated ; this, when treated with conc. nitric acid, leaves a white residue of germanic oxide. Analyses of the germanium silver compound, and the results obtained by passing the gas over finely divided sulphur show that the formula is more likely to be GeH_4 than GeH_2 or Ge_2H_4. This is in agreement with the composition of *germanium tetraethide*, $Ge(C_2H_5)_4$, prepared by C. Winkler, and described by L. M. Dennis and F. E. Hance. Analyses by R. Schenck and A. Imker, and F. Paneth and co-workers agree with the formula GeH_4. R. Schenck and A. Imker's value for the vap. density was 76·93 in agreement with the theoretical value 76·50. L. M. Dennis and co-workers also obtained confirmatory results, since a litre of the gas at 0° and 760 mm. weighed 3·420 grms. ; and the sp. gr. of the liquid at −142° was 1·523 ; F. Paneth and co-workers prepared germane by the action of sulphuric acid on an alloy of germanium and zinc or magnesium ; and R. Schenck and A. Imker prepared it by the action of hydrochloric acid on an alloy of magnesium and germanium in a stream of hydrogen, and cooling the product in liquid air ; some *germanium-chloroform* or *trichlorogermane*, $GeHCl_3$, was produced by cooling the gas with a freezing mixture before it is cooled by liquid air. The hydride has a nauseating odour, and the purified product has a m.p. −165°. R. Schenck and A. Imker found the b.p. to be −90° to −91°, in agreement with the value −88·5° obtained by F. Paneth and co-workers ; and the −90° of L. M. Dennis and co-workers. A lower value, −126°, was obtained with a sample which had been in contact with mercury over-night, and consequently was partially decomposed. F. Paneth and co-workers obtained −164·5° for the m.p. ; and 3·65 Cals. for the mol. heat of evaporation. The vap. press., p, was found by R. Schenck and A. Imker to be :

	−155°	−140°	−120°	109°	−101°	−96°	−92°	−91°	90°
p . . .	2	15	83	190	336	485	648	714	782 mm.

The general reactions of the gas show that it is endothermic, and analogous in properties to the hydrides of arsenic, antimony, tin, and bismuth. E. Paneth and co-workers said that the hydride is unusually stable, being unaffected by 50 per cent. potassium hydroxide soln., or phosphoric oxide, and requires a relatively high temp. for its decomposition. J. H. Müller and N. H. Smith prepared the hydride by the action of electrolytic hydrogen, sodium amalgam, or aluminium and dil. alkali-lye, on a soln. of a germanium salt. The germanium mirror obtained like the arsenic mirror in testing for arsenic, enables 0·00006 grm. of germanium to be detected.

L. M. Dennis, R. B. Corey and R. W. Moore prepared some germanium hydride by the action of aluminium on a soln. of germanium dioxide in potash-lye ; and by the electrolysis of a 50 per cent. soln. of orthophosphoric acid using a germanium rod as cathode, and condensing the gas from the cathode by liquid air. The yields in both cases are small. They obtained a mixture of germanium hydrides by the method employed by A. Stock and C. Somiesky for the silicon hydrides (q.v.). The fractional distillation of the condensate in the vessel cooled by liquid air furnished a mixture of mono-, di-, and tri-germanes. 67·5 grms. of a magnesium-germanium alloy, containing 40·5 grms. of germanium, yielded 7·15 grms. of monogermane, 2·12 grms. of digermane, and 0·43 grm. of trigermane. This corresponds with the conversion of only 22·7 per cent. of the germanium into the hydrides, and of this 73·6 per cent. appeared as monogermane, 22 per cent. as digermane, and 1 per cent. as trigermane. Part of the 77·3 per cent. of the unconverted germanium may form compounds analogous with the so-called silico-oxalic acid.

The fractionation product of the mixed liquid, collected between −77° and −72°, consisted of **digermane,** or **germanoethane,** Ge_2H_6, in agreement with the analyses, and with the vap. density 6·7405—theory for digermane gave 6·743. The sp. gr. of the colourless liquid is 1·98 at −109° ; the m.p. is −109°, and the b.p. 29° at 760 mm. The vap. press., p mm., is :

	−98·2°	−72·0°	−53·5°	−44·0°	−34·0°	−22·0°	−18·0°	−6·0°	0°
p	3·0	6·0	15·9	31·4	48·4	87·6	105·4	189·0	243·1

When exposed to air, digermane became first yellow, then light brown, and finally a dark brown solid. It is not usually spontaneously inflammable in air, but by admitting air suddenly to the gas under reduced press., a flash of light occurred, and the walls of the vessel acquired a dark brown film. The vap. ignites with almost explosive violence, and the liquid burns with great rapidity, forming a reddish-brown solid with black and white streaks. When oxygen is admitted into a vessel containing digermane, no reaction occurs at first, but in about 10 mins. a white solid is formed, which, in about an hour, becomes yellow. No reaction occurs at first with water, and the two liquids do not mix ; after a time, however, a white gelatinous substance forms in the water layer, and this then becomes yellow and light brown ; with 33 per cent. soda-lye, a colourless combustible gas is given off ; monogermane does not react with lye of this conc. even when heated. Digermane mixes with carbon tetrachloride, heat is evolved and a clear colourless soln. is formed. When this has stood in contact with air a white solid is deposited, this slowly turns yellow and then disappears.

The fractionation of the residue left after the removal of digermane furnished a colourless liquid the analysis of which agreed with **trigermane** or **germanoproptane,** Ge_3H_8. The vap. density 10·005 corresponds with Ge_3H_8 which has a theoretical value 10·07. The sp. gr. of the liquid is 2·20 ; the m.p., −105·6° ; and the b.p., 110·5°. The vap. press., p mm., is :

	2·4°	10·0°	30·0°	45·0°	55·0°	70·3°	90·3°	104·0°	111·5°
p	15·5	21·3	50·9	90·9	138·5	238·5	429·2	620·4	773·4

When exposed to air, trigermane quickly turned to a white solid ; and when a few drops of trigermane are ignited on a watch-glass, the liquid burns with a yellow flame, forming a voluminous, pulverulent residue with black, brown, and white streaks. The reactions with oxygen, water, and carbon tetrachloride resemble those with digermane, but with 33 per cent. soda-lye no reaction was observed between the two liquids.

§ 5. The Germanium Oxides and Hydroxides

Germanium forms two oxides, GeO and GeO$_2$. The former, **germanium monoxide** or **germanous oxide**, GeO, was prepared by C. Winkler[1] by fusing powdered germanium with borax, and washing the cold mass with water. It formed a reddish-yellow **germanous hydroxide**, Ge(OH)$_2$, which was converted into the oxide by heating it in a current of carbon dioxide. It was also made by heating germanic oxide with magnesium ; but W. Biltz could not make it by heating germanic oxide with germanium : Ge+GeO$_2$=2GeO. C. Winkler made it by the action of alkali hydroxide on germanium chloroform :

The germanium chloroform was treated with water to form an oxychloride ; the product was treated with sodium carbonate until it had an alkaline reaction, and evaporated almost to dryness on a water-bath. The product was washed with water three times— a part passed into soln. The soln. filtered badly because it choked up the pores of the paper. The precipitate was washed with alcohol, and finally with ether. When dried in vacuo, the hydroxide was obtained which passed into the oxide when heated in a stream of carbon dioxide.

Germanium monoxide is a dark grey powder, which, according to W. Biltz, is not volatile. The oxide readily dissolves in hydrochloric acid, forming germanous chloride. The soln. gives a yellow hydroxide when treated with alkali hydroxide ; a white ferrocyanide, with potassium ferrocyanide ; and a brown sulphide, with hydrogen sulphide. It reduces soln. of chromates and permanganates ; precipitates gold from auric chloride soln. ; and reduces soln. of mercuric chloride to mercurous chloride and to mercury. Litmus is at once bleached by the soln. The yellow hydroxide, prepared as indicated above, is either soluble in or is peptized by water, forming a yellow liquid which remains turbid after passing through filter-paper. An excess of alkali gives a similar result. The hydroxide is often superficially white owing to oxidation. If the hydroxide be heated with the liquid from which it has been precipitated, it becomes red. A. Hantzsch attributes this to the tautomeric change : Ge(OH)$_2$⇌O+Ge(OH)H, the latter formula representing the germanium analogue of formic acid—**germanoformic acid**, H.GeO.OH. The hypothesis is strengthened by the fact that germanous hydroxide is produced by the action of water on germanium chloroform : HGeCl$_3$+2H$_2$O=3HCl+HGeO.OH, followed by H.GeO.OH⇌Ge(OH)$_2$. The hydroxides of zinc, beryllium, lead, tin(ous), and germanium were shown by A. Hantzsch to behave like feeble acids whose strengths increase in the order given. Germanous hydroxide thus appears to be rather weaker than acetic acid. The acidity of the hydroxides of germanium, tin, and lead increases with decreasing at. wt. ; and seems to be connected with their ability to form quadrivalent compounds. The solubility of germanous hydroxide in alkali hydroxides is attributed to the formation of soluble **germanites** ; and the germanites are considered to be salts of germanoformic acid, H.GeO.OH.

C. Winkler prepared **germanic oxide** or **germanium dioxide**, GeO$_2$, by heating the metal in oxygen ; by roasting the sulphide in air ; by heating the metal with nitric acid ; by treating the sulphide with sulphuric acid, and calcining the product at a red heat. The decomposition of the germanium tetrachloride by water gives an oxide of a high degree of purity : GeCl$_4$+2H$_2$O=4HCl+GeO$_2$. The addition of ammonia lessens the amount of oxide dissolved by the hydrochloric acid

produced by the hydrolysis. The colloidal product is difficult to wash, and the last traces of chlorine are retained very tenaciously. C. Winkler purified the oxide extracted from the mineral, by dissolving it in hydrofluoric acid, and adding the calculated quantity of potassium fluoride required to form potassium fluogermanate, K_2GeF_6. This salt is purified by crystallization. The oxide cannot be obtained satisfactorily by heating the fluogermanate with sulphuric acid because of the volatility of germanium fluoride; it is therefore fused with sodium carbonate and sulphur as indicated in connection with the extraction of germanium. J. H. Müller and H. R. Blank purified the dioxide in the following manner :

Germanium dioxide can be freed from arsenic and other metals by repeated distillation in chlorine from hydrochloric acid soln., and precipitation from the distillates by hydrogen sulphide. The final distillation of the tetrachloride gives a product from which oxide can be prepared by simple hydrolysis. Germanium dioxide made by the hydrolysis of the tetrachloride contains detectable amounts of chloride, and the oxide prepared by the oxidation of the sulphide by nitric acid retains appreciable amounts of sulphur. It is usually assumed that these impurities will be removed by continued ignition, but larger quantities of the oxide are not readily freed from either of them by this method. Germanic oxide may therefore readily be prepared free from either chlorides or sulphates, but it is rather difficult to eliminate both of these impurities from the same portion of material. Sulphates can be removed by ignition alone, provided it be continued for a very long time at a very high temp. Prolonged ignition over a Meker burner was found insufficient when 10 grms. or more of the oxide were involved. Immediate fusion at about 1100° also failed to produce a pure oxide, as sulphates could be detected in the aq. soln. of the resulting glass. Ignition above 950° for about 36 hrs. in an electric furnace, completely removed the sulphates from 10 or 15 grms. of the oxide. The ignition described above was found insufficient for the removal of the last traces of chlorine from 10–15 grms. of material. Heating the oxide in a current of superheated steam slowly carries out much hydrogen chloride, as may be seen by treating the condensed steam with silver nitrate. Repeated moistening of the oxide with water, followed by evaporation and ignition at 950°, is an effective method. It seems probable that the small quantity of water tenaciously held by germanium dioxide up to 900° plays an important part in completing the hydrolysis of the chloride, for unless this water was repeatedly renewed and expelled, the oxide did not lose all of its retained chlorine even at 950°.

Germanium dioxide is a dense, white, gritty powder which can be crystallized by very slowly evaporating the aq. soln. The microscopic vermiculites so obtained belong, according to K. Haushofer, to the rhombic system. A. E. van Arkel, and V. M. Goldschmidt studied the X-radiogram. C. Winkler found the sp. gr. to be 4·703 at 18°; and L. F. Nilson and O. Pettersson, the sp. ht. between 0° and 100°, 0·1291. C. Winkler said that the oxide can be heated to bright redness without change; and W. Biltz, that the oxide can be melted to a clear liquid without volatilization, at 1025°. E. L. Nichols gave 1400° for the m.p., but J. H. Müller and H. R. Blank found the oxide melts between 1090° and 1100°. J. O. Perrine observed no sign of the excitation of fluorescence by the X-rays. E. L. Nichols studied the emissivity of the oxide between 837° and 1370°. J. H. Müller and H. R. Blank found that on ignition between 226° and 1100°, part of the oxide becomes insoluble in water and inert towards acids and alkalies, and it becomes soluble again after fusion. The speed of conversion of the soluble to the insoluble form increases to a maximum at 380°, and then decreases to the m.p. It is suggested that there are at least two allotropic forms of germanium dioxide, and that the conversion from the soluble to the insoluble form never reaches 100 per cent.; they found that like other oxides, GeO_2 when heated shows in its radiation deviations from black-body intensity. At temp. near 900°, the blue part of the spectrum is radiated at black-body intensity, the red at only 4 per cent. of black-body intensity; at about 1225°, the radiation is of black-body composition but about 10 per cent. of black-body intensity; at 1370°, the red is of black-body intensity, but the blue much weaker. A hydrogen flame impinging on GeO_2 excites luminescence—pale blue-green at low temp., red at higher.

According to C. Winkler, the calcined oxide is somewhat soluble in water, for

100 parts of water at 20° dissolve 0·405 part of the oxide, and at 100°, 1·05 parts. J. H. Müller and M. S. Iszard gave 10·9 grms. per litre at 100°. The ignited oxide, said J. M. van Bemmelen, forms an emulsion with water, and this becomes clear when heated owing to the formation of a colloidal soln. The evaporation of the aq. soln. furnishes the anhydrous oxide. The aq. soln. has an acid reaction. Neither *germanium hydroxide*, Ge(OH)$_4$, nor *germanyl hydroxide*, GeO(OH)$_2$, has been definitely prepared. C. Winkler found that the product obtained by the hydrolysis of the tetrachloride when dried over sulphuric acid contained 3·63 per cent. of water; when dried at 100°, 3·19 per cent.; at 200°, 2·32 per cent.; and at 250°, 1·74 per cent. By oxidizing germanium sulphide in ammoniacal soln. with hydrogen dioxide, the product dried at 100° contained 1·22 per cent. of water. The precipitates obtained by adding ammonia or alkali carbonates to a soln. of a salt of germanium contained alkali and carbon dioxide; germanates appear to be formed. J. M. van Bemmelen passed carbon dioxide into a soln. of germanium dioxide in soda-lye and obtained a colourless, amorphous precipitate which, when dried in air, had a composition ½Na$_2$O.GeO$_2$.1·8H$_2$O; when dried over sulphuric acid, it retained a mol. of water; and when dried at 100°, 0·4 mol. Very little water was lost between 100° and 150°; but at 160°, all the water was expelled. No carbon dioxide was present. It was very difficult to remove the alkali by washing. L. M. Dennis and co-workers found that dehydration is complete in 3 hrs. at 950°, and no volatilization occurs below 1250°.

According to C. Winkler, when germanium dioxide is heated in a stream of hydrogen it is slowly reduced to the metal—*vide supra*. The oxide readily dissolves in hydrofluoric acid—*vide infra*. When hydrochloric acid is poured over the dioxide, and the mixture evaporated to dryness, a large proportion of the germanium is volatilized as chloride. The dioxide is but sparingly soluble in acids. The oxide is amphoteric, and the acidic character preponderates. J. M. van Bemmelen found that the crystalline dioxide dissolves neither in conc. sulphuric acid nor in the acid diluted to ·H$_2$SO$_4$.4H$_2$O; a little is taken up when the mixture is warmed. Hydrated germanium dioxide retains sulphuric acid very tenaciously. According to C. Winkler, when germanium dioxide or germanium is heated with potassium iodide or sulphur no chemical change occurs. Germanium dioxide is reduced by charcoal in the reducing flame, and at the same time, a white deposit of germanium dioxide is formed on the charcoal; the dioxide readily dissolves in the borax bead, and the cold glass is colourless whether produced in the oxidizing or reducing flame; the dioxide also dissolves readily in molten microcosmic salt. When the dioxide is moistened with a soln. of a cobalt salt and heated, no coloration is developed. L. M. Dennis and co-workers found that germanium dioxide is readily reduced when heated with aluminium. According to C. Winkler, molten alkali hydroxides or carbonates readily dissolve germanium dioxide. The cold products are readily soluble in water. When the conc. aq. soln. is treated with an acid, germanium dioxide is precipitated, but not from dil. soln. The feebly acidified soln. is not precipitated by potassium hydroxide, but a partial precipitation of germanium dioxide occurs by the addition of sodium carbonate or hydrocarbonate, ammonia, or ammonium carbonate. The precipitates dissolve when warmed with an excess of the precipitant, and are re-deposited on cooling.

F. S. Hammett and co-workers [2] compared the toxicity of arsenic trioxide and germanium dioxide when applied subcutaneously to albino rats. Arsenic trioxide usually produced fatal results in a dose of 8 mgrms. per kilogram of body weight; and sublethal doses produce sloughing at the point of injection. Germanium dioxide in doses as great as 180 mgrms. per kilogram of body weight produced neither death nor any apparent evidences of harmful effects; sloughing did not occur at the point of injection. Hence, with respect to toxicity, germanium resembles the members of the tin group of elements rather than those of the arsenic group. G. H. Bailey and co-workers found 4 mgrms. to be a toxic dose for rabbits.

§ 6. The Germanium Fluorides

C. Winkler [1] could not prepare **germanous fluoride** or **germanium difluoride,** GeF_2, but when potassium fluogermanate is warmed in a stream of hydrogen, there is evidence of the formation of some germanous fluoride because when the dark brown mass is treated with water some germanium is deposited, and the soln. furnishes germanous sulphide, GeS, when treated with hydrogen sulphide.

Anhydrous **germanic fluoride** or **germanium tetrafluoride,** GeF_4, has not been obtained of a high degree of purity. Germanium dioxide dissolves in 20 per cent. hydrofluoric acid with hissing and the evolution of much heat; with 40 per cent. acid the reaction is so violent that some oxide may be projected from the containing dish. If a soln. be evaporated over sulphuric acid, a syrupy liquid is formed which gradually solidifies, forming a white, imperfectly crystalline mass of *trihydrated* germanium tetrafluoride, $GeF_4.3H_2O$. It readily melts in its water of crystallization on the water-bath, and it becomes covered with a pellicle of oxide while some hydrogen fluoride escapes; at a higher temp., about half the germanium present is volatilized as fluoride, and the other half remains as oxide. The trihydrate is very hygroscopic; it dissolves in water, and the soln. is probably hydrolyzed because it attacks glass. When the soln. is heated some germanium fluoride is volatilized along with the hydrogen fluoride. When the trihydrate is heated in a stream of carbon dioxide, the anhydrous fluoride appears to be formed. The hydrated fluoride is formed when a mixture of germanium dioxide, calcium fluoride, and sulphuric acid is distilled. C. Winkler also said that germanium tetrafluoride is volatilized when a mixture of potassium fluogermanate and sulphuric acid is heated until the acid begins to evaporate. G. Krüss and L. F. Nilson said that germanium dioxide is formed—*vide infra*. C. Winkler said that the proportion of fluoride formed in this reaction depends on the proportion of the acid which determines the speed of the decomposition.

When the vap. of germanium tetrafluoride is passed into water, a soln. of germanic oxide or acid is formed and of **hydrofluogermanic acid,** H_2GeF_6. This colourless liquid has an acidic reaction, and when evaporated over sulphuric acid, it furnishes a syrupy liquid, evolving germanium tetrafluoride, and at the same time deposits needle-like crystals of germanic oxide. Hydrofluogermanic acid appears to be volatile at ordinary temp., and it can be distilled in vacuo over a water-bath; but its b.p. lies above that of water. The acid has not been isolated. The soln. attacks glass. The addition of a small proportion of ammonia produces no change, but with a large proportion white germanium dioxide is precipitated; the precipitate dissolves when the soln. is warmed, and is re-deposited on cooling. When the acid soln. is treated with potassium hydroxide, or a potassium salt, **potassium fluogermanate,** K_2GeF_6, is formed as a white precipitate. C. Winkler obtained the same salt by adding potassium chloride to a soln. of the oxide in hydrofluoric acid; G. Krüss and L. F. Nilson prepared potassium fluoride, and they added that the salt can be recrystallized from its aq. soln. J. H. Müller described the preparation

of the salt of a high degree of purity. According to G. Paykull and W. C. Brögger, the white, crystalline powder consists of hexagonal crystals isomorphous with ammonium fluosilicate. The axial ratio is $a:c=1:1\cdot6078$. The double refraction is negative. C. Winkler said that the salt melts to a white glass at a dull red heat; and at a full red heat, white vap. are evolved, and the product obtained after heating for one hour gives, with water, white germanium dioxide and an alkaline liquid. G. Krüss and L. F. Nilson said that it does not melt at a red heat; and is not decomposed. According to C. Winkler, 100 parts of water at 180° dissolve 0·575 part of salt, and at 100°, 2·93 parts; G. Krüss and L. F. Nilson said that 100 parts of water at 18° dissolve 0·542 part of salt, and at 100°, 2·58 parts. C. Winkler noted the formation of germanous fluoride (q.v.) when potassium fluogermanate is heated to redness in a stream of hydrogen. If the aq. soln. be mixed with an excess of sulphuric acid and evaporated on a water-bath, G. Krüss and L. F. Nilson said that long acicular crystals are formed, probably those of a double salt, *potassium germanium sulphate*. This decomposes when further heated, and particularly if mixed with ammonium carbonate, forming a mixture of germanium dioxide and potassium sulphate. C. Winkler said that when potassium fluogermanate is heated with sulphuric acid germanium tetrafluoride is volatilized. A. Skrabal and J. Gruber prepared **rubidium fluogermanate,** Rb_2GeF_6, by dissolving germanium dioxide in hydrofluoric acid and adding a soln. of rubidium fluoride; **cæsium fluogermanate,** Cs_2GeF_6, was made in a similar way.

§ 7. The Germanium Chlorides

Two chlorides have been prepared, $GeCl_2$ and $GeCl_4$; a hydrotrichloride, $GeHCl_3$, analogous in composition with chloroform, $CHCl_3$; and an oxychloride—possibly $GeOCl_2$. C. Winkler [1] obtained impure germanous chloride, or germanium dichloride, $GeCl_2$, by the action of hydrogen chloride on germanous sulphide, GeS; and a soln. of germanous chloride is probably formed when germanous oxide or sulphide is dissolved in hydrochloric acid. C. Winkler said that when germanium is heated in a stream of hydrogen chloride either germanous chloride or germanium chloroform is produced—both hypotheses proved to be correct. The product is a mixture.

As indicated above, C. Winkler found that if hydrochloric acid be added to an aq. soln. of germanium dioxide and the soln. evaporated, all the germanium is volatilized as **germanium tetrachloride,** $GeCl_4$. The chloride is obtained by heating germanium in a stream of chlorine, and the product purified by shaking it with mercury to remove free chlorine. J. H. Müller could not remove the last traces of arsenic by distillation in a stream of chlorine and hydrogen chloride. L. M. Dennis and F. E. Hance said that the reaction between germanium and chlorine begins at about 80°; there is a rapid combination at 180°; and at 360°, the metal glows brilliantly in chlorine gas. The fused germanium freed from adherent flux, and pulverized, was placed in an alundum boat, and heated in a glass tube. The exit was connected with a U-tube having a bulb at the bend to collect the liquid germanium tetrachloride which was condensed in the tube surrounded by a freezing mixture of ice and salt. The product was freed from chlorine by passing air through the liquid contained in a flask with a long neck packed with glass wool and the side-arm of the flask connected with a U-tube cooled by ice and salt. This prevented an undue loss of tetrachloride. In about 7 hrs. the free chlorine was removed. The liquid was then fractionally distilled and the fraction boiling at 85·6° collected. C. Winkler also

made the tetrachloride by heating a mixture of powdered germanium or germanium sulphide and mercuric chloride.

According to C. Winkler, germanium tetrachloride is a colourless, mobile liquid which fumes strongly in contact with air. The vap. coats glass with a white pellicle. Its sp. gr. is 1·887 at 18°; L. M. Dennis and F. E. Hance gave 1·874 at 25°/25°; and A. W. Laubengayer and D. L. Tabern, 1·879 at 20°/20°. I. I. Saskowsky found the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements to be 1·45. C. Winkler gave 86° for the b.p.; L. M. Dennis and F. E. Hance, 86·5° at 760 mm.; and A. W. Laubengayer and D. L. Tabern, 83°; C. Winkler said that the liquid is perceptibly volatile even at ordinary temp., and L. F. Nilson and O. Pettersson found the vap. press,, p atm., to be:

	10·7°	30·0°	50·0°	70·7°	185·0°	215·0°	255·0°	276·9°
p . . .	0·073	0·151	0·33	0·67	7·0	15·0	28	38

R. Lorenz and W. Herz discussed these data. The vap. density at 301·5° was 7·45, and at 739°, 7·44; the value calculated for $GeCl_4$ is 7·43. The critical temp. is 276·9°. C. Winkler said that the liquid can be cooled to −100° without freezing; L. M. Dennis and F. E. Hance gave −49·5°±0·2° for the m.p. The index of refraction was 1·3606 at 27°; A. W. Laubengayer and D. L. Tabern gave 1·4683 at 12·5°, and 1·4602 at 27°. W. Hampe found that the liquid is a non-conductor of electricity at ordinary temp. and at its b.p. M. E. Lear gave 2·6 at 30° for the dielectric constant.

If the liquid be kept in an imperfectly closed vessel, small crystals are formed near the surface of the liquid; C. Winkler thought that they might be those of a hydrate. When a mixture of the vap. and hydrogen is passed through a red-hot tube, a small proportion is reduced to germanium, and a little germanous chloride, while the greater proportion is not altered. Germanium tetrachloride is decomposed by water, much heat is developed, and germanium dioxide is formed. If the tetrachloride be dropped into cold water, each drop in falling becomes covered with a white film which becomes thicker and partially protects the interior; and there is a crackling sound emitted which persists several hours if the liquid be not shaken. L. M. Dennis and F. E. Hance found that when dropped into conc. sulphuric acid at room temp., the germanium chloride sinks to the bottom of the vessel and is not attacked; H. Friedrich said that germanium tetrachloride can be distilled from the conc. acid without decomposition. L. M. Dennis and F. E. Hance found that when the tetrachloride sinks to the bottom of conc. nitric acid, there is a slow reaction at the surface of contact, and the tetrachloride becomes yellow. Agitation hastens the reaction. With dil. nitric acid (2 : 1), the decomposition is slow and uniform. Much heat is developed when ammonia gas is passed into the tetrachloride, and a white precipitate is developed. A 1 : 4 soln. of potassium hydroxide develops so much heat that some tetrachloride is distilled off before the reaction is complete. The germanium dioxide which is formed dissolves in an excess of the reagent, and is re-precipitated by carbon dioxide. The tetrachloride is soluble in absolute alcohol, carbon disulphide, carbon tetrachloride, benzene, chloroform, and ether without decomposition; but the soln. in acetone forms an orange-coloured liquid.

C. Winkler found that when germanium is gently heated in a current of hydrogen chloride, the metal becomes red-hot, hydrogen is evolved, and two liquids of almost the same sp. gr. are produced. They are separated by fractional distillation. The lighter one is the oxychloride—*vide infra*. The analysis of the heavier, colourless liquid corresponds with **germanochloroform** or **germanium hydrotrichloride,** $GeHCl_3$. L. M. Dennis and co-workers obtained it by the action of hydrogen chloride on germanous chloride. V. Meyer found its vap. density at 178° is 5·55, when the value calculated for $GeHCl_3$ is 6·23. C. Winkler found the b.p. to be 72°; L. M. Dennis and co-workers gave 75·2°; −71° for the m.p.; 1·93 for the sp. gr. of the liquid; and a litre of the gas weighs 7·980 grms. The compound fumes strongly in air, possibly owing to the formation of an oxychloride. The vapour of the

hydrotrichloride coats glass with a white pellicle, and colours cork an intense red, while it decomposes when strongly heated—probably $2GeHCl_3=Ge+GeCl_4+2HCl$. If 3 vols. of water be added to the liquid, a white substance, possibly an oxychloride, is formed; if another 3 vols. of water be added, a yellow precipitate is formed; and on the addition of still more water and boiling the mixture, the orange precipitate becomes reddish-brown and germanous hydroxide (q.v.) is formed: $2GeHCl_3+4H_2O=6HCl+2Ge(OH)_2$. The white precipitate also passes into germanous chloride in contact with much water. Germanium hydrotrichloride dissolves in hydrochloric acid with the development of heat, and when the soln. is diluted with water germanous hydroxide is precipitated. With sodium carbonate it forms germanous hydroxide: $2GeHCl_3+3Na_2CO_3+H_2O=6NaCl+3CO_2 +2Ge(OH)_2$. Germanium hydrotrichloride acts as a reducing agent. G. T. Morgan and H. D. K. Drew found that it reacted with acetylacetone, forming germanium *bis*acetylacetone dichloride.

Germanium hydrotrichloride reacts with oxygen when exposed to air, forming a white substance which C. Winkler regarded as **germanium oxychloride**, or **germanyl chloride**, $GeOCl_2$; the reaction is symbolized: $2GeHCl_3+O_2=2GeOCl_2+2HCl$. If a current of air or oxygen be passed through germanium hydrotrichloride, heat is developed, hydrogen chloride is given off, and the soln. becomes turbid. On standing, the emulsion separates into a liquid which collects at the bottom of the vessel. Its formation by the action of hydrogen chloride on germanium is indicated above, and is presumably the result of the presence of air in the gases. The colourless, non-fuming liquid boils above 100°; it is not miscible with germanium hydrotrichloride, and is not decomposed by distillation. It has not been obtained in a state of purity.

§ 8. Germanium Bromide and Iodides

C. Winkler [1] prepared **germanium tetrabromide**, $GeBr_4$, from its elements. L. M. Dennis and F. E. Hance found that when the bromine vap. is passed into a glass tube containing an alundum boat with pulverulent germanium, the action begins at 25° but soon ceases; when the temp. is gradually raised, slow union occurs at 180°; and at 220°, germanium tetrabromide is rapidly produced, and collects in the condensing tubes. The liquid distillate forms a yellowish-white solid below 26°. Agitation with mercury to remove the free bromine gave a product which retained a little mercury. The product was therefore purified by fractional distillation, and the fraction boiling at 183°–186° was collected. C. Winkler obtained tetrabromide by heating germanium tetrachloride and potassium bromide in a sealed tube—the reaction was incomplete—and by heating a mixture of germanium and mercuric bromide.

C. Winkler said that germanium tetrabromide is a colourless, mobile, strongly fuming liquid which freezes to a crystalline mass at about 0°. L. M. Dennis and F. E. Hance found that it shows to a marked degree the phenomenon of undercooling, for the undisturbed liquid could be cooled to −18° without solidification. The m.p. is 26·1° and the corrected b.p. 185·9° at 760 mm. The observed b.p., $\theta°$, is

corrected for the barometric press., p, at 0°, by adding on 0·0001235(760–p)(273+θ). The crystals are flattened octahedra, and isotropic, thus belonging to the cubic system. The sp. gr. is 3·1315 at 25°/25°; the index of refraction, 1·6296 at 20·70°; 1·6283 at 22·20°; and 1·6269 at 25°. I. I. Saskowsky found the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements to be 1·21. L. M. Dennis and F. E. Hance found the sp. electrical conductivity to be less than 0·000078 mho at 30°.

C. Winkler said that the tetrabromide is decomposed by water, forming germanium dioxide. L. M. Dennis and F. E. Hance also studied the hydrolysis and noted a slight crackling sound when the tetrabromide is dropped into water. No action was observed when the tetrabromide was allowed to stand in contact with sulphuric acid for several days, at room temp. With nitric acid, the tetrabromide becomes yellow and turbid, and a layer of white germanium dioxide is formed between the two liquids; in about 15 mins. the tetrabromide has changed to a black colour and there is a copious evolution of nitric oxide. Dry ammonia forms a white solid in contact with germanium tetrabromide. An aq. soln. of potassium hydroxide (1 : 4) reacts at once with the tetrabromide, and heat is evolved; germanium oxide separates out, but immediately passes into soln. Carbon dioxide precipitates the oxide from the soln. of potassium germanate. Germanium tetrabromide is soluble in absolute alcohol, carbon tetrachloride, benzene, and ether without decomposition; but the soln. in acetone slowly liberates bromine. G. T. Morgan and H. D. K. Drew found that it reacted sluggishly with acetylacetone, forming germanium *bis*acetylacetone dibromide.

L. M. Dennis and F. E. Hance found that in the preparation of germanium tetraiodide by the action of the vap. of iodine on germanium at 360°, yellow crystals of **germanous iodide,** or **germanium diiodide,** GeI_2, collected between the red tetraiodide and the germanium. C. Winkler made some **germanic iodide** or **germanium tetraiodide,** GeI_4, by heating a mixture of germanium tetrachloride and potassium iodide in a sealed tube—the reaction was incomplete, and he could not separate the germanic chloride and iodide by fractional distillation. He also prepared the iodide by heating pulverulent germanium in the vap. of iodine carried along by a slow current of carbon dioxide. It was necessary to sublime the product repeatedly in an atm. of carbon dioxide to eliminate the iodine. L. M. Dennis and F. E. Hance observed that the reaction begins at 212°, and at 360°, the combination is rapid. During the resublimation of the product, they noticed that the colour gradually changed from a bright red to a chocolate-brown, showing that the compound is partially decomposed when sublimed.

C. Winkler said that germanium tetraiodide has an orange colour; L. M. Dennis and F. E. Hance said that while the powder is orange, the fused iodide in lump form is coral-red at ordinary temp. At –185°, the colour is canary-yellow; at –50°, buff; at –10°, orange; at 35°, salmon; at 50°, brick-red; at 90°, red; and at 144°, ruby-red. The crystals are octahedra with the plane angles 60°; and being isotropic without birefringence, they must belong to the cubic system. The sp. gr. is 4·3215 at 26°/26°. C. Winkler, and L. M. Dennis and F. E. Hance found the m.p. to be 144°; and the first-named said that on cooling it forms a crystalline mass with a marked decrease in volume. It boils at 350°–400°, forming a yellow vap., and as the iodide condenses some violet iodine vap. remains, indicating that the iodide has suffered some dissociation. L. F. Nilson and O. Pettersson said that the compound is not decomposed at 440°, but dissociates at a higher temp. They measured the vap. density, and found 20·46 at 440°, when the calculated value for GeI_4 is 20·09; at 658°, the vap. density is 17·19, indicating that dissociation has taken place. L. M. Dennis and F. E. Hance obtained an analogous result, and showed that the agreement between the observed and calculated values does not indicate that there is no dissociation. The vap. was shown to be a mixture of germanium diiodide and iodine : $GeI_4 \rightleftharpoons GeI_2 + I_2$.

C. Winkler said that the vap. of germanium tetraiodide is inflammable in air;

and that a mixture of the vap. with air explodes feebly with a reddish flame, forming germanium dioxide and iodine. He added that the tetraiodide is *sehr hygroskopisch*, and deliquesces in air, forming a brown liquid coloured by free iodine and which gradually forms white germanium dioxide owing to the volatilization of the iodine. He found a 50 per cent. gain in weight the first day, and a steady loss during the next 18 days, so that the residue weighed about a fourth as much as the original sample. *Au contraire*, L. M. Dennis and F. E. Hance observed no signs of a gain or loss of weight when exposed in air for 2 days; and only a slight decrease in weight after 5 months' exposure owing to the formation of a slight white incrustation. Presumably the hygroscopic sample was contaminated with something other than the tetraiodide. C. Winkler found that the tetraiodide is decomposed by a small proportion of water, forming germanium dioxide, which dissolves when more water is added, forming a clear, colourless soln. having an acid reaction. The soln. acquires a coloration on standing owing to the separation of iodine from the hydriodic acid. L. M. Dennis and F. E. Hance obtained analogous results, and found that the tetraiodide is not affected by conc. sulphuric acid at room temp. during 24 hrs.; but at 85°, iodine was slowly liberated. At room temp., conc. hydrochloric acid slowly dissolves the tetraiodide, dissolution being complete after some weeks. The tetraiodide is decomposed under conc. nitric acid, with the evolution of nitric oxide. The acid acquires a black coloration. When dropped into conc. aq. ammonia, the compound is at once decomposed and decolorized, forming a white solid; with dry ammonia gas, a white powder is slowly formed which is soluble in water. When placed in a soln. of potassium hydroxide (1 : 4), germanium tetraiodide is slowly dissolved. The tetraiodide dissolves in benzene, in monochlorobenzene, and in carbon disulphide, forming an orange-red soln.; in methyl alcohol, forming a deep orange soln.; in ethylene chloride, and in carbon tetrachloride, forming light orange soln.; and in ethylene glycol, and in ethylene chlorohydrin, forming light yellow soln. These soln. underwent no visible change on standing 4 months; but there was a distinct change of colour with soln. of the tetraiodide in hexane (orange-red), chloroform (pale orange), nitrobenzene (orange-red), petroleum (pink), butanol (orange), and glacial acetic acid (pale yellow), owing to the liberation of iodine. Soln. in acetone, ether, turpentine, oil of lavender, absolute alcohol, isopropyl alcohol, pyridine, and amyl alcohol decomposed at once.

§ 9. The Germanium Sulphides

Germanium forms two sulphides, **germanous sulphide,** or **germanium monosulphide,** GeS; and germanic sulphide or germanium disulphide, GeS_2. C. Winkler[1] made the former by heating to redness a mixture of germanium disulphide with an excess of germanium in a current of carbon dioxide. The product appeared partly as dark grey crystals, and partly as a reddish-brown powder. He obtained a crystalline mass of the monosulphide by heating the disulphide in a stream of hydrogen—hydrogen sulphide was evolved. If argyrodite be similarly heated in a stream of hydrogen, germanium monosulphide appears as a brown dust the microscopic appearance of which has been described by K. Haushofer. C. Winkler observed that when hydrogen sulphide is passed into a soln. of germanous oxide in hydrochloric acid, reddish-brown, amorphous germanous sulphide is precipitated. The amorphous powder readily forms with water an orange-red or brown, opalescent, **colloidal germanium monosulphide.** It can be kept without change

in a closed vessel, but in air it is oxidized and loses its colour.   Acids flocculate the
suspended colloid.

Germanium monosulphide appears as a brown powder and in crystals of different
habits ; those prepared by heating the disulphide in hydrogen appear in thin
plates with a lustre and colour recalling the appearance of iodine, or iron glance.
According to A. Weisbach, the plates are doubly refracting and either monoclinic
or rhombic.   L. F. Nilson and O. Pettersson found that germanous sulphide melts
to a dark liquid which, in turn, freezes to a crystalline mass.   The vap. density is
3·54 at 1100°, and 3·09 at 1500°.   The monosulphide dissociates at a white heat.
According to C. Winkler, when germanium monosulphide is heated in air, sulphur
dioxide is evolved and germanium dioxide is formed.   When heated in a stream of
hydrogen, most of the monosulphide is volatilized undecomposed, but in the
hottest part, a part of the monosulphide is reduced forming octahedral crystals of
germanium.   The amorphous sulphide readily dissolves in hot conc. hydrochloric
acid with the evolution of hydrogen sulphide and the formation of germanous
chloride ; crystalline germanous sulphide dissolves in hydrochloric acid with
difficulty.   Germanous sulphide dissolves vigorously in molten potassium hydroxide,
and it is readily soluble in an aq. soln. of potassium hydroxide, especially when
warmed, any germanium present remains undissolved.   When the soln. is acidified,
amorphous, reddish-brown germanous sulphide is precipitated.   Amorphous
germanous sulphide dissolves in a soln. of ammonium sulphide, $(NH_4)_2S$, forming
a thiogermanate, and the soln. deposits white germanic sulphide when treated
with an acid.   Crystalline germanous sulphide is said to be insoluble in a soln.
of ammonium sulphide.   When the sulphide is mixed with potassium nitrate and
heated, it detonates.

According to C. Winkler, when acid soln. of germanium dioxide are treated with
hydrogen sulphide, a white precipitate of **germanic sulphide** or **germanium disul-
phide,** GeS_2, is formed.   An aq. soln. of germanium dioxide gives no precipitate with
hydrogen sulphide, but when the soln. is acidified with sulphuric or hydrochloric
acid, a white turbidity appears which settles to a voluminous white precipitate.
With a feebly acidified soln., the germanium is only partially precipitated as
sulphide ; for complete precipitation a strongly acidified soln. is necessary.   Acetic
acid and other organic acids will not do.   Germanium disulphide is precipitated
when an alkali sulphogermanate is treated with an acid, and for complete precipita-
tion a large excess of sulphuric or hydrochloric acid is necessary, and the soln. should
be sat. with hydrogen sulphide.   The sulphide precipitated from acid soln. is
peptized when washed, forming **colloidal germanium disulphide,** which is opalescent
after long standing and repeated filtration—one such soln. had one part of germanium
sulphide in 221·9 parts of water.   The sol is flocculated by acids, and with metal
salt soln. it gives colorations characteristic of the metal sulphides.   It also decom-
poses, giving off hydrogen sulphide.

Germanium disulphide shows but little tendency to crystallize or volatilize.
When the white amorphous disulphide is heated in a stream of carbon dioxide, it
shrinks very much and acquires a yellow or yellowish-grey colour ; if the temp. is
raised to bright redness, a part is volatilized, forming a white coating which is partly
crystalline.   When germanium disulphide is heated in air, it forms sulphur and
germanium dioxides, and possibly also an *oxysulphide* since the complete elimination
of sulphur is not possible by mere roasting.   When heated with hydrogen, the
monosulphide is formed (*q.v.*).   The dried and calcined sulphide decomposes in moist
air ; and when the moist disulphide is dried on a water-bath some hydrogen sulphide
is given off.   Acids favour the reaction.   When the disulphide is evaporated with
hydrochloric acid, the germanium is volatilized as tetrachloride ; when evaporated
with sulphuric acid, until a large proportion has been driven off, germanium dioxide
is formed and it retains some adsorbed acid very tenaciously ; and when treated with
nitric acid, there is a vigorous reaction and the resulting germanium dioxide retains
some sulphuric acid.   Aqua regia dissolves germanium disulphide with the separa-

tion of sulphur. The disulphide dissolves readily in aq. ammonia, and in soln. of the alkali hydroxides, or alkali sulphides. Presumably **sulphogermanates** are formed, but none has been isolated. The soln. of germanium disulphide in potassium sulphide gives precipitates—possibly sulphogermanates—when treated with salts of the heavy metals. If the soln. of germanium disulphide in potassium hydroxide be treated with chlorine or bromine, sulphur is separated. The soln. of germanium disulphide in aq. ammonia is oxidized by hydrogen dioxide without the separation of sulphur. *Argyrodite* and *canfieldite* can be regarded as a basic **silver sulphogermanate,** a derivative of the acid $Ge(SH)_4.2H_2S$. S. L. Penfield [2] represented its composition by Ag_8GeS_6, and that of canfieldite, by $Ag_8(Sn,Ge)S_6$—*vide supra*. A. Weisbach described a steel-grey mineral as monoclinic, but S. L. Penfield showed that the crystals belong to the cubic system. The sp. gr. is 6·085–6·111 ; and the hardness 2·5. E. T. Wherry found argyrodite to have poor qualities as a radio-detector. O. Pufahl's mineral *germanite* previously indicated has a composition $Cu_5(Cu,Fe)_6AsGeS_{12}$, and sp. gr. 4·46.

C. Winkler [3] reported the formation of a white *germanous phosphate* when a soluble phosphate is added to a germanous salt soln. ; but otherwise *germanium phosphates, nitrates, carbonates, and sulphates* have not been described.

CHAPTER XLVI

TIN

§ 1. The History of Tin

IT is generally believed that tin is one of the metals which has been known since very ancient times, and that this metal was employed in the arts at the time of Herodotus, Homer, and Moses. The proof of the great antiquity of tin, however, is not so convincing as in the case of copper, silver, gold, mercury, lead, and iron. The metal tin was not found native by the ancients, and they could have obtained it only by extraction from its ore. It is true, however, that the ore is found near the surface of the earth, and that it gives up its metal more readily than some of the ores of the other metals. Thus, according to J. F. Reitemeyer,[1] the early Britons smelted the ore by a very simple process :

> They placed the ore in a hole dug in the ground, and laid wood between and around it. They then set fire to the wood. The fire smelted the ore. The slag was run from the molten metal through a pipe or furrow into a second hole. Many of these slag-hearths are still found in Cornwall. The whole smelting process was as effective as it was simple ; proof of this is found in the fact that the slag residues do not contain sufficient ore to warrant a second separation by more modern methods.

Tin ores occur in only a few countries which were not readily accessible to the Romans or Greeks, and accordingly, as J. Beckmann has pointed out, it appears probable that the metal would be scarce and costly among these people. Assuming that the metal believed to be tin was really such, it does not appear to have been accounted of much value. The few references to tin do not allude to objects made of this metal as being valued possessions. Again, although more durable than lead or copper, vessels of tin are very rarely found among Greek or Roman antiquities under conditions where vessels of lead and copper are comparatively common.

There are good grounds for doubting whether the scholars have been always correct in translating the ancient terms by what is now connoted by the word " tin." Moses, in the book of *Numbers* (**31.** 22), gives a list of the metals then known, and his term *bedil* was translated κασσίτερος in the old Greek versions of the Hebrew books ; and *cassiteros* in turn was translated *stannum* in the Latin versions. Stannum was rendered by *tin* in Low German and English ; by *tenn* in Swedish ; by *Zinn* in High German ; by *estain* in French ; by *estano* in Spanish ; and by *stagno* in Italian. Pliny, in his *Historia naturalis* (**34.** 47), regarded tin as a variety of lead. He said :

> There are two kinds of *plumbum*—*nigrum*, and *candidum* or *album, i.e.* black lead, and shining or white lead. The *plumbum candidum* is the most valuable, and it was called *cassiteros* by the Greeks. There is a fabulous story told of their going in quest of it to the islands in the Atlantic Ocean, and of its being brought in boats made of osiers covered with hides. The *plumbum candidum* occurs as a black sand found on the surface of the earth, and is to be detected only by its weight ; it is mingled with small pebbles, particularly in the dried beds of rivers. The miners wash the sand, which is then melted in the furnace and becomes converted into *plumbum album.*

Pliny's *plumbum candidum* was no doubt tin just as his *plumbum nigrum* was lead. Pliny then described the production of lead from ores containing both lead and silver. He said that the metal which first becomes liquid in the furnace is called *stannum*, the next is *argentum*, and part which remains in the furnace is called *galena*. These three substances were regarded by Pliny as the component parts of the ore. When the galena was once more fused it furnished *plumbum nigrum* or lead. The scholars tell us that the Phœnician word *stan* is the source of the Latin word *stannum*. Several conjectures have been made as to the meaning of *stannum*. It is evidently not *tin* nor a peculiar metal, but rather, as emphasized by J. Beckmann, a mixed or compounded metal or alloy analogous to the German *Werkblei*, or the English *base-bullion*. This view was taken by G. Agricola, C. Encelius, G. Fallopius, L. Savot, M. A. Bernia, and J. Jung. Pliny described Roman vessels made of copper and coated with *stannum* ; and mentioned the use of an imitation *stannum* made from a mixture of two parts of *plumbum candidum* with one part of *aes candidum*. J. Beckmann believed that the *cassiteron* of the Greeks was equivalent to the Roman *stannum*, being a mixture of lead, silver, and other accidental metals. The term *cassiteron* is used by Homer, *Iliad* (11. 25 ; 18. 565, 574, 612 ; 22. 561); and Pliny said : " *Plumbum candidum* was esteemed in the days even of the Trojan war, a fact, attested by Homer, who called it *cassiteros*." The fourth and sixth century translators of Dionysius' Περιήγησις, written about the fourth century, rendered the Greek *cassiteros* by *stannum* ; and, according to J. Beckmann, the cumberous term *plumbum candidum* began to be exchanged for *stannum* ; and as tin was becoming common, the older meaning of *stannum* was soon forgotten.

J. P. Rossignol said that the history of tin among the ancient peoples can be divided into two periods. The first corresponds with the exploitation of tin in Asia ; and the second with the importation of the metal from Great Britain by the Phœnicians. According to M. Berthelot, the analyses of articles of copper alloys found in Mesopotamia, belonging to a period 4000 B.C., show that tin was not used in their manufacture ; but the analysis of an Egyptian bronze mirror belonging to a period 1600 B.C., shows that tin was present. Bronze seems to be an Oriental discovery—*vide* copper (3. 21, 1)—and, according to O. Olshausen, objects made of tin are very rarely found associated with vessels of the Bronze Age. A. H. Church said that the use of tin by the Egyptians, 700–600 B.C., has been proved by the finding of a strip of tin free from lead and silver, in the wrappings of an Egyptian mummy of an age not later than 600 B.C. M. Winer also refers to the use of tin by the ancient Egyptians. F. von Richthofen said that the Chinese bronze industry flourished 1800–1500 B.C., so that tin must have been known in China in that period. This subject has been discussed by K. Faulmann, and F. Lenormant.

According to H. Dufrené, the Egyptian word for tin is *khespet* ; and, according to E. Reyer, the old Indian name for tin is *naga* ; the Persian name, *aonia* ; the Chaldean and Hebrew, *anak* ; and the Æthiopian, *naak*. P. Diergart has discussed the etymology of the term *tin* W. C. Borlase considered that κασσίτερος is a word of Phœnician or Chaldean origin. From the assumption that *kastira* is a Sanscrit word, it has been inferred that κασσίτερος was derived from *kastira*, and that the earliest tin must have come from India ; but F. C. Movers, and F. Lenormant, hold that the term *kastira* was derived from κασσίτερος when the metal was carried from the West to India through the ordinary trade channels.

There are only scanty references to the tin trade of the Phœnicians, the Greeks, the Gauls, and the Romans. Herodotus (3. 115) said : " I am not acquainted with the Cassiterides Islands from whence comes our tin." There are also references by Hesiod (258) ; by Aristotle, *De mirabilibus auscultationibus* (81) ; by Strabo, *Geographica* (3. 2, 9) ; and by Cæsar, *De bello gallico* (5. 12). The fabulous story narrated by Pliny—*vide supra*—could very well refer to the transport of tin or tin ore from the Scilly Islands and Cornwall by vessels resembling the coracles of the ancient Britons. About 1000 B.C., the Phœnicians appear to have worked tin

mines in Cornwall, and they seem to have conveyed there a body of colonists who established an emporium. The metal was also obtained from the inhabitants by barter, and imported into Greece and Asia. They called the Scilly Islands and shores of Cornwall, the Cassiterides or Tin Islands—Dionysius, in his Περιήγησις, written near the beginning of the fourth century, called them Hesperides.

Ezekiel (27. 12) refers to the tin (bedil) of the Phœnicians, and to the commerce with this metal at Tyre. The Phœnicians' trade with Britain has been discussed by W. C. Borlase, R. Edmonds, S. Greathead, C. Hawkins, J. Henry, A. H. L. Heeren, J. Kendrick, G. C. Lewis, G. Rawlinson, E. Reyer, C. R. G. Napier, J. Rhys, C. D. Saunders, L. Simonin, G. Smith, J. Taylor, A. Tylor, R. N. Worth, etc. W. D. Cooley said :

Tin in all ages has been a principal export of India. It is enumerated as such by Arrian, who found it abundantly in the ports of Arabia, at a time when the supplies of Rome flowed chiefly through that channel. The tin mines of Banca are, probably, the richest in the world. But tin was unquestionably brought from the West at a later period.

The work of Periplus of Arrian, on which this opinion is based, is supposed by W. Vincent to have been written about A.D. 64, that is, about the time of Pliny's Historia naturalis. G. Smith's examination of the available evidence has shown that W. D. Cooley's opinion is highly improbable ; that tin was invariably exported from Egypt to the East; that the Phœnicians, finding tin in Britain 1500–1200 B.C., carried the metal into the Eastern markets. Diodorus Siculus, in his Bibliotheca historica (5. 347, 361), written about 30 B.C., said that the Britons carried tin from Cornwall to the island called Ictis, when it was conveyed abroad by Gallic merchants to different parts of Italy. W. C. Borlase argued that this Ictis must have been nearer to Cornwall than the Isle of Wight, and he assumed that the Ictis is a generic term for a peninsula, bay, or a depôt for merchandise.

The assumption that the Cassiterides was really Britain is supported by T. R. Holmes, E. O. von Lippmann, S. Reinach, etc. Some hold that the locality was off the north-west coast of Spain. This view is supported by quotations from writers prior to A.D. 150. Many of these, however, might have been able to say with Herodotus (3. 115), " Nor am I better acquainted with the Islands called Cassiterides from which we are said to get our tin."

Strabo alone, in his Geographica (15. 10), has said that tin is found in Drangiana ; but if this country be a part of Persia, all travellers—e.g. J. Chardin, and J. B. Tavernier—say that tin is not found anywhere in the Persian Empire ; and if Drangiana be part of India, then Pliny, in his Historia naturalis (34. 17), asserted that no tin had then been found in that country. The production of tin in Spain is mentioned by Strabo and Pliny ; in Lusitania by Pliny, and Strabo ; in Iberia by Diodorus Siculus ; and in Artabra by Strabo. The exploitation of tin in ancient France was discussed by L. Davy, L. Simonin, E. Mallard, S. R. Pattison, and A. G. Werner. The history of tin in general has also been treated by G. Bapst, M. Gsell, J. P. Rossignol, F. X. M. Zippe, A. Rössing, E. Beyer, E. Reyer, A. Frantz, B. Neumann, H. Dufrené, E. O. von Lippmann, A. Mongez, etc.

The Spanish tin mines appear to have been abandoned under the government of the Moors. Much of the world's supply of tin about the thirteenth century came from Cornwall, but about that time, tin mines were discovered in Saxony and Bohemia, and not at the end of the eighth century, as stated by W. Hagec. According to M. Paris, a Cornishman fled to Germany because of a murder, and there discovered tin in 1241. The story has not been authenticated, and is not mentioned by J. F. Gmelin ; while P. von Lichtenfels said that the German tin mines were discovered in 1146 near Grauppen. The subject has been discussed by E. Reyer, and A. Schmidt. It is not known when tin was first obtained from the Malay States and the East Indies, but, according to E. O. von Lippmann, the source of the metal is mentioned by Arabian writers of the eighth and ninth centuries. J. Beckmann indicates a number of sixteenth-century writers who mentioned East Indian tin, and Malacca tin. He added that the mines at Banca

were discovered in 1711, and said that there are ten pits being there worked by the Chinese in 1776. J. A. Schuurman wrote on the history of the Banca tin mines. According to W. Gowland, tin was not used much by the early Japanese. A general idea of the early smelting furnaces is described in connection with lead. J. J. Becher claimed to have been the first to use coal in Cornwall for smelting tin ore ; but, added J. Percy, the claim is not substantiated.

The early Greek alchemists called tin *Hermes* ; but about A.D. 500, the alchemists called it *Zeus* or *Jupiter*, and represented it by the symbol ♃, which is said to represent the thunderbolts of Jupiter. This idea is perhaps a good illustration how easily the mind can believe there is a connection between things which have no relation to each other. According to J. Beckmann,[2] the origin of the symbol for tin is not, as A. Y. Goguet supposed, the remains of an Egyptian hieroglyph used by the Arabians ; rather is it a corruption of the first and last letters of ζεύς, for in the fourth century *Mathesis* of J. Firmicus Maternus, the capital Z is used, and in order to render the abbreviation more distinct, the last letter ς was sometimes added at the bottom. Owing to the property possessed by tin of forming brittle alloys with other metals it was also called *diabolus metallorum*—the devil of the metals. The alchemists of the Middle Ages observed many other properties of tin—*vide* the oxide, chloride, and sulphide. The Latin Geber, in his *Summa perfectionis magisterii*, probably written about the twelfth century, said :

I intimate to the sons of learning that tin is a metallic substance which is white, but not pure white ; it has a little ring, and emits a creaking sound ; it partakes of a little earthiness ; and possesses in its root both hardness and softness ; it melts rapidly without catching fire ; it does not take cupellation—*cineritium et cementum non exspectans* ; and it is extensible when hammered. Its vice is that, when alloyed, it makes every metallic body brittle excepting Saturn and pure Sol.

§ 2. The Occurrence of Tin

Tin, though one of the common metals, is the most sparsely distributed metal in common use. The known workable deposits of gold cover one and a half million square miles, while the known workable deposits of tin cover but one-twelfth of this area. There is scarcely a country where gold has not been or might be profitably obtained ; tin is confined to about a dozen districts in the world. The tin deposits of Cornwall so long famed in history are nearing exhaustion ; the same might be said of the deposits in Bohemia, Tuscany, South Spain, and the Pyrenees. There are, indeed, comparatively few known workable deposits of tin in the World.—ANON.

Although so common and well known a metal tin is really a scarcer element than many less familiar elements usually ranked with the scarce and rare elements— *e.g.* cerium and yttrium, lithium, beryllium, titanium, zirconium, vanadium, etc. According to the estimates of J. H. L. Vogt,[1] the igneous rocks on the earth's crust contain $n \times 10^{-5}$ per cent. of tin ; F. W. Clarke and H. S. Washington estimated $n \times 10^{-6}$ per cent. For the amount in the earth's crust, the estimate is $0.0000x$ per cent. The most abundant source of tin is the oxide, cassiterite, found in association with granitic rocks. The greater portion of the world's supply is derived from alluvial deposits in which the cassiterite originally occurred in veins and lodes in highly acid igneous rocks. The tinstone of the detrital deposit is associated with other durable constituents of the rock—quartz, ilmenite, tourmaline, and topaz. The formation of tin deposits was discussed by W. R. Jones, R. H. Rastall, etc.

A general idea of the distribution of the tin deposits will be obtained from Fig. 1. Tin deposits are thus widely distributed, but 85 per cent. of the world's supply comes (i) from the area embracing the deposits at Malay, Siam, and China ; and (ii) from the deposits at Bolivia.[2]

Only a small proportion of the world's supply comes from Europe. Cornwall ³ is practically the only source of tin in *Great Britain,* although a small proportion comes from the adjoining parts of Devon. In 1919, Cornwall produced 5156 tons of ore with 66·4 per cent., and Devon, 28 tons. The tin-bearing lodes on the *Bohemian* and *Saxony* sides

of the Erzgebirge were an important source of tin in mediæval times, but they are now mainly of historical interest being practically exhausted. There is a tin-smelting industry in *France*, but the production is small and erratic. Ore occurs at Montebras, Vaulry, Cieux, Chanteloube, Meymac, Puy les Vignes, and Charrier. *Holland* is not a producer, but is rather a distributing centre for the tin produced in Dutch East Indies. Iron and tin were mined in early times at Campiglia Marittima, Tuscany, in *Italy*, and the deposits were rediscovered in 1871. The production is very small. Tin has been produced in *Portugal* from the time of the Phœnicians. The output from deposits at Mirandella, Montesinhos, Parada, Coelhoso, Marao Angueria, and Valle Seixo ; and near Ramalhoso, Vizeu, and Belmonte, is small. The deposits in *Spain* are also historically famous, having been worked by the Phœnicians and the Romans. The output is now small. The deposits occur mainly at Penuta, Romilo, Verin, Monertey, Almaraz, Lumbrales, Viana del Bollo, Pontevedra, Terrubias, and Santo Tomé de Rozadas near Salamanca, San Isodoro and Marinera near Cartagena, and near Almeria. Very little tin is produced in *Russia*, but a number of deposits are known on the rivers Onon, and Ignoda, and their tributaries.[4] There are mines at Olovianaia, north-west of Nerchinsk, and in Onon-Borzia, in the Transbalkans province of Siberia. There is an occurrence at Pitkaranta, Finland ; and deposits at Sossnowics and Dombroff, *Poland*.

In *Asia*, *China* furnishes about seven per cent. of the world's supply of tin. Cassiterite
FIG. 1.—The Geographical Distribution of the Chief Deposits of Tin Ore.

occurs in the provinces of Hunan, Yunnan, Kwangsi, Kwangtung, and Tukien. Ninety per cent. of the 8000 tons of crude tin produced per annum in China comes from the Kochiu district of Yunnan in Southern China. There are deposits in Kowloon, Hong Kong. Tin has been worked from ancient times by the Chinese in the French colony, *Indo-China*. There is a little tin ore in the neighbourhood of Kaobang, north of Tonkin, and there are deposits at Ban ta coua, Laos, and in the neighbourhood of Pia-Ouac. *Japan* has a very small output. Deposits occur in Taniyama, Satsuma ; Kyushu and Nagao in Osumi ; Iwato and Mitate in Hyuga ; and Kiura in Bungo ; Nayegi in Mino ; and Sudzukoya in Hitachi. There is a great stanniferous belt stretching from Banca through the Malay peninsula into Burma. The chief production of *Siam* is from the detrital deposits on the west side of the main range, in Monthon Puket, and smaller amounts come from Chumporn Nakorn, Stamarat, and Patani. Some is obtained by dredging at Tongkah Harbour, and Renong. The ore occurs in the valley of the Nam Sak river. In the *Dutch East Indies*, the principal centres of the tin industry are the islands Banca, Billiton, and Singkep. Some tin is also produced at Siak, on the River Indrigiri, Sumatra, and on the Karimon Islands. At Singapore and Penang, in the *Straits Settlements*, are large smelteries which treat the ores from the surrounding countries. Malacca is the only producer of ore ; there is a deposit at Chin-Chin. The *Federated Malay States* are the largest producers of tin ore, and that of an exceptionally good quality. The mines in Perak produce more than those in Selangor, Negri Sembilan, and Pahang combined. In the Kinta district of Perak, there are mines at Kampar, Malim Nawar, Sungei Siput, Gopeng, Pulai, Ulu Piah, Tambun, Tanjong, Rambutan, Menglembu, Penkalan, Lahat, Rotan Dahan, Redhills, Pusing Lama, Pusing

Baharu, Siputeh, Tronoh, and Tanjong Toh Allang. There are also pipes at Ayer Dangsang, and Changkat Pari. In the Larut district, Perak, there are mines at Selama and Blanda Mabok. There is a lode on Gunong Paku, Intan ; and veins of ore at Bruseh. In Selangor there are stanniferous deposits near Tanjong Malim, Kalumpang, Serendah, Kuala Lumpur, Salak, Sungei Besi, Rawang, Kepong, Setapek, Ampang, and Serdang. In Negri Sembilan, there are lodes at Titi, on the Triang and Kenaboi rivers, at Kuala Pilah Pantai, Rasa, Chukong, Gebok, and Lukut. In the Pehang district there are deposits at Bentong, Tras, Machi, and Belat, and on the Kuantan river and its tributaries Blat, and Sungei Lembing. The *Unfederated Malay States* have tin deposits at Muar, Batu Pahat, and Kota Tinggi in Johore ; at Kuala Muda, Kulim, Krian, and Kubang Pasu in Kedah ; at Bukeit Yong, Palua Chondong, and Uli Kelatan and on the Nenggiri in Kelantan ; at Setul in Perlis ; at Bundi, Sungei Ayam, Sungei Sendok, Sungei Paka, Sungei Kajang, and Bukit Tawang, and on the Dungan river in Trengganu. There are no deposits of commercial importance in *Ceylon*, though cassiterite occurs in the gem-gravels of Balangoda. The production of tin ore in *India* is small ; Burma and the Southern Shan States are responsible for most of the tin. Stanniferous deposits occur at Maliwun, Karanthuri, Yaungwa, Bokpyin, Yengan, Manoron, Mergui, Thabalik, and the Great Tenasserim Valley, King's Island, Kissering, Davies Island, Amherst, Tavoy, Chota Nagpur, Narunga, Chappatand, and the Palanpur State.

In *Africa*, tin ore was formerly smelted in Bauchi, *Nigeria*, by a primitive method regarded as a family secret. It is now produced at Naraguta, Ngell, Bukuru, Forum, Ropp, etc., on the Bauchi Plateau. Tinstone also occurs in the Ningi and Burra hills ; in the Vere hills, and the Shebshi hills ; and near Gadama, Fagam, Jemaa, Amari, Gantam, Aribi Eri, and Akwa Ibami. In the *Gold Coast*, stream tin occurs in the Winnebah district, in Mankofa, and the Mankwadi. In *Rhodesia*, there are deposits in the Enterprise, Ndanga, Mazoe, and Shamva districts, in the Odzi Reserve, and along the Tsungiwesi and the Umniati rivers. In *South-West Africa*, formerly a German colony, the tin-bearing belt extends from Otjimboyo to Uis ; and there are deposits at Ameib, Dawib, Aubinhonis, Tsomsaub, Neineis, Uis, Kawab Otjumue, and Kohero East. In the Union of South Africa the chief tin-mining districts are in the Eaterberg area, Western Transvaal, and Swaziland. There are deposits at Annex Langverwacht, Vredehoek, and Tygerrberg in *Cape Province* ; in Umfuli in Natal ; in Zaaiplaats, Roodepoort, Groenfontein, Solomon's Temple, Doornhoek Kromkloof, Welgevonden, Zwartkloof, Elandsfontein, Witfontein, Newbery, Rhenosterpoort, Quaggafontein, Weynek, Leeuwpoort, Enkeldorm, Vlaklaagte, Roodepoortje, Mutue Fides, and Stavoren in the *Transvaal*. The districts of Mbabane and Forbes Reef are the two important tin-bearing districts in *Swaziland*. In *Portuguese East Africa* there are deposits at Chimoio, and Moçambique ; and in *Belgian Congo* there are deposits at Busanga, Muika, Kiambi, Muanga, and Mulongo.

In *America*, there is no production of tin in *Canada*, but deposits of cassiterite occur at New Ross, Nova Scotia ; in New Brunswick, British Columbia, and the Yukon district. Very little tin ore is produced in the *United States*. Deposits of economic importance have been found at Alaska ; and ore occurs in the Hot Springs district, at Gaffney, Carolina ; in the Black Hills, South Dakota and Wyoming ; Mount Franklin, Texas ; in Lander County, Nevada ; Shenandoah Valley, Virginia ; San Diego County, and Temescal, California ; etc. Cassiterite is widely distributed in *Mexico*, and has been worked by natives in Durango, Jalisco, Guanajciato, San Luis Potosi, Aguas Calientes, and Coalhuila. Tin mining in Mexico has been carried on since the Aztec period. The annual output is small. The output of tin from *Bolivia* is second only to that of the Federated Malay States. The Bolivian mines are situated on the Eastern Cordillera, and the high plateau between Eastern and Western Cordillera. Most ore comes from Potosi, and other centres are Araca, Cruro, Machacamarca, Huanuni, Llallogua, Uncia, Sala Sala, Chocaya, and Chorolque. At the time of the Spanish domination, the Bolivian mines were worked only for gold, silver, and copper. The rejected tin ores accumulated on dumps and in old stopes, and they have been proved valuable acquisitions. Most Bolivian ore now comes from simple tin lodes. In the *Argentina*, cassiterite occurs at Catmarca and La Rioja. Bohemian ore is exported from *Chile* and *Peru*, but there is no noteworthy production in these countries.

Tin mining began in **Australasia** in 1872. In *New South Wales*, the chief centres are Emmaville and Tingha, ore occurs at Elsmore, Ardlethan, Newstedd, Stannifer, Stanborough, Cope's Creek, Catarrh Creek, Rose Valley, Ruby, Maryland, Herding Yard, Cemetry, Wilson's Downfall, Wylie, Two Mile Creek, Bookookoorara Creek, Mount Tallabong, Lachlan Valley, Burra Burra, Mandanah, Albury, Jingellie, Germanton, Tumbarumba, Wagga Wagga, Bungonia, Jindabyne, Euriourie, Poolamacca, near Byron Bay, near Port Macquarrie, near Seal Rocks, at Shell-harbour, Termeil, Oban, etc. Very little tin ore is produced in the *Northern Territory*. There are deposits at Mount Wells, Burrundei, Horseshoe Creek, Maranboy, Hayes' Creek, Rum Jungle, etc. The tin fields of *Queensland* are in the north with the exception of those at Stanthorpe and Nanango. There are the tin fields in Herberton, Chillagoe, Annan River, Stannhills, Lode Hill, Kangaroo Hills, Charters Towers. etc. In *South Australia*, cassiterite occurs near Earea Dam, Tarcoola. In *Tasmania* there are mines near Middlesex, in the Ben Lomond and

Avoca districts. The Mount Bischoff mine has been the most important mine in Tasmania.
There are mines in the North Dundas tin field, and in the X-River district ; in the Zeehan
Field ; in the Heemskirk district and in the Stanley River and Mount Balfour districts.
The output of tin from *Victoria* is comparatively small. There are deposits at Glen Wills,
Beechworth, Eldorado, Chiltern, Stanley, Rutherglen, Koetong, Cudgewa, Toora, Tin
Creek, Agnes River, Bruthen, Gembrook, Neerim, Darnum, Bunyip River, Tarago River,
Upper Yarra, Mount Cudgewa, Mount Wills, Pilot Range, Mitta Mitta, Eskdale, Tallandoon,
and Mount Singapore. In *Western Australia* there are tin fields in Greenbushes, and
Pilbara. A deposit occurs in West Kimberley. *New Zealand* does not produce tin ore,
but deposits have been reported in various localities on the West Coast—Mokihinui, Canoe
Creek, Clark River. It has been reported at Slaty Creek, near Lake Brunner, Hauraki,
and Port Pegasus, Stewart's Island.

Between 1742 and 1759, Cornwall alone produced 39,600 tons of metal at an
average price of £80 2s. per ton ; between 1840 and 1847, 51,768 tons at an average
price of £99 per ton ; in 1860, 6656 tons at £136 3s. per ton ; in 1872, 9560 tons
at £152 15s. per ton ; in 1878, 10,106 tons at £65 12s. 3d. per ton. The world's
output in tons of 2240 lbs. was :

	1880	1890	1900	1910	1918	1920
Output .	38,321	55,098	80,824	104,073	122,513	119,211
Average price }	£91 5s. 0d.	£97 13s. 3d.	£133 11s. 6d.	£155 6s. 2d.	£329 11s. 2d.	£296 1s. 7d.

The total world's production of 142,000 tons (of 2240 lbs.) of tin ore, in 1924,
was distributed as follows :

Malay States	.	.	.	.	46,913	Bolivia	31,610
Australia .	.	.	.	.	3,069	Dutch East Indies . . .	31,558
Nigeria .	.	.	.	.	6,162	China	7,000
Cornwall .	.	.	.	.	1,986	Siam	7,950
Union of South Africa	.	.	1,162	Belgian Congo, etc. . . .	645
India	.	.	.	.	1,375	Portugal, Spain	400

Native stannum is of no commercial significance. Reports of the occurrence
of native tin were made by J. Matthesius,[5] and J. C. Richter. In 1750,
J. G. Wallerius said that *stannum nativum* is very rarely seen ; and T. Bergman
added, in 1780 : " Many testimonies concur in asserting that tin is found native
in England ; but I have never seen any specimens of it." C. Linnæus, and
R. J. Haüy had doubts about its occurrence. Neither A. G. Werner, nor A. Estner
mentioned native tin. J. B. L. Romé de l'Isle had a specimen alleged to be native
tin ; but, added L. A. Emmerling, the specimens of native tin supposed to have
been found in Cornwall and in Bohemia are probably derived from the remains
of old tin smelteries. Now, however, there is no reason for doubting that tin
sometimes occurs naturally in the metallic state. Native tin occurring with gold
in Russia has been described by C. von Tscheffkin,[6] R. Hermann, and
P. von Jeremejeff ; from Bolivia, by D. Forbes, F. Nies, H. Reck, and
A. W. Stelzner ; from French Guiana, by A. Damour ; from Guanajuanto, Mexico,
by A. Frenzel ; and from Pennsylvania, by C. M. Wetherill. J. D. Dana con-
sidered that these reports are not unimpeachable ; but there is no doubt about the
occurrence of tin in rounded grains, 0·1–1·0 mm. in diameter, along with platinum,
iridosmine, gold, copper, cassiterite, and corundum in the washings from the
tributaries of the Clarence river, near Oban, New South Wales. Besides cassiterite
a little *stannite, tin pyrites,* or *bell-metal ore,* $SnS_2.Cu_2S.FeS$, has been worked in
Bolivia, New South Wales, and Tasmania. Other tin minerals of no economic
importance are : *cuprocassiterite,* $4SnO_2.Cu_2Sn(OH)_6$; *frankeite,* $Pb_5Sn_2Sb_2S_{12}$;
cylindrite, $Pb_6SnSb_2S_{12}$; *teallite,* $PbSnS_2$; *plumbostannite,* $Sn_2Sb_2Pb_2(Fe,Sn)_2S_{11}$;
canfieldite, $Ag_8(Sn,Ge)S_6$; *nordenskjöldine,* $CaSnO_4(BO)_2$; and *stokesite,*
$CaO.SnO_2.3SiO_2.2H_2O$.

Tin occurs in small quantities as an accessory constituent of a number of other minerals,
Thus, J. J. Berzelius,[7] G. Jenzsch, H. Rose and R. Weber, A. E. Nordenskjöld, R. Hermann.
E. S. Dana and O. D. Allen, C. A. Schaeffer, T. S. Hunt, H. Müller, J. L. Smith, F. A. Genth,
and E. S. Hall and A. Smith reported up to 2 per cent. of stannic oxide in specimens of

columbite from different localities. O. Hauser and L. Finckh found it in *plumbocolumbite*. G. Jenzsch, C. F. Chandler, L. Weiss and M. Landecker, H. Rose and R. Weber, J. C. G. de Marignac, C. F. Rammelsberg, A. Arzruni, and A. G. Maitland up to 6 per cent. of stannic oxide in various samples of *tantalite*. J. J. Chydenius reported tin in *yttro-tantalite ;* A. E. Nordenskjöld, in *ixiolite ;* A. Damour, in tin oxide in *titaniferous iron ore ;* R. Hermann, in *ferroilmenite ;* G. Friedel and F. Grandjean, in *rutile ;* R. Hermann, in *ilmenorutile ;* J. W. Mallet, and A. Damour, in *euclase ;* H. Rose and R. Weber, C. F. Rammelsberg, W. E. Hidden and J. W. Mallet, and R. Hermann, in *fergusonite ;* R. Hermann, J. T. Donald, G. C. Hoffman, E. S. Dana and E. H. Swallow, in *samarskite ;* A. Thorpe, and C. W. Blomstrand, in *monazite ;* F. Zambonini, in *delorenzite ;* O. Hauser, in *risörite ;* J. C. G. de Marignac, in *œschinite ;* W. J. Knowlton, in *cyrtolite ;* H. Sjögren, in *fredricite ;* C. W. Blomstrand, in *polycrase ;* S. R. Paykull, in *eucrasite ;* J. W. Mallet, in *sipylite ;* C. F. Rammelsberg, in *ferberite ;* A. E. Nordenskjöld, in *tapiolite ;* F. P. Möller, in *tritomite ;* A. E. Nordenskjöld, and C. F. Rammelsberg, in *hjelmite ;* C. F. Rammelsberg, in *tyrite ;* A. E. Nordenskjöld, in *malacone ;* E. Linnemann, and G. Woitschach, in *zircon ;* F. A. Genth, and H. Traube, in *scheelite ;* J. L. Smith, O. D. Allen, and F. A. Genth, in *hatschettolite ;* K. F. Föhr, and H. Trenkler, in *phonolite ;* A. E. Nordenskjöld, and F. P. Dunnington, in *microlite ;* F. Farsky, in *olivine ;* G. J. Brush, in *pyrophillite ;* C. A. de Gouvenain, and S. Meunier, in *kaolin ;* G. vom Rath, in *cryolite ;* H. Schröder, in *mica ;* F. Sandberger, in *lepidolite ;* G. Sobrero, in *mangano-epidote,* and *pyrolusite ;* A. Piutti and E. Stoppani, in *pyrite ;* J. M. Saitao, in *fahlerz ;* A. des Cloizeaux, in *sperrylite ;* J. H. Collins, in *zinc blende ;* H. J. Sjögren, in *thalenite ;* and L. Hundeshagen, in *tourmaline.*

A. Bergeat [8] observed tin in the exhalations from Stromboli. The presence of stannic oxide has been reported in numerous meteorites.[9] Spectral observations by J. N. Lockyer,[10] C. Hutchins and E. L. Holden, and H. A. Rowland have shown that tin occurs in the atm. of the sun ; and similar observations by J. Lunt showed that it is present in the atm. of some stars. Traces of tin have been reported in a number of natural waters by J. J. Berzelius,[11] C. F. Rammelsberg, etc. Water distilled through a still-head and worm of tin was shown by H. Fleck [12] to contain traces of that metal ; J. and H. S. Pattinson found tin in commercial antimony, and H. Hager, in commercially pure hydrochloric acid. According to O. Hehner, every article of food preserved in a tin canister dissolves some of the tin coating of the metal and becomes contaminated with tin in quantities depending upon the acidity of the material, the time of contact, and the quality of the tinplate. Condensed milk takes up a mere trace, acid fruits quite tangible amounts. From every sample of tinned food, without exception, weighable traces of tin can be separated. A. P. Smith, A. R. Leeds, R. Kayser, F. Wirthle, L. Medicus, H. Serger, E. F. Kohman and N. H. Sanborn, K. B. Lehmann, A. J. J. Vandevelde, E. Ungar and G. Bodländer, F. A. Norton, and J. Attfield found it in preserved fruits ; A. Sam, in preserved beans ; E. Ungar, in asparagus ; J. B. M. Coebergh, in canned spinach ; R. Kayser, in eels ; T. Günther, A. Rössing, and G. Salomone, in preserved fish ; T. L. Phipson, and J. Mayrhofer and A. Hilger, in sugar ; G. Gimel, in yeast ; and A. Eckardt, in animal and vegetable substances. H. Serger discussed the occurrence of tin in canned foods ; A. Beythein, in cosmetics.

§ 3. The Extraction and Purification of Tin

Tin ore is usually treated by a series of operations to concentrate the cassiterite and remove a large proportion of gangue, and associated impurities. The resulting *black tin* is smelted by dry methods, and then refined. Wet processes and electrolytic methods are confined to the extraction of the metal from tin-scrap. Manufacturing details belong to metallurgical works such as :

H. Lewis, *Metallurgy of Tin*, New York, 1911; H. Mennicke, *Die Metallurgie des Zinns*, Halle a. S., 1910; P. J. Thibault, *Metallurgy of Tin*, Sydney, 1908; A. G. Charleton, *Tin Mining, Dressing, and Smelting*, London, 1884; P. van Diest, *Banca and its Tin Stream Works*, Truro, 1867; S. Fawns, *Tin Deposits of the World with a Chapter on Tin Smelting*, London, 1907; A. H. Sexton and J. S. G. Primrose, *The Common Non-ferrous Metals*, Manchester, 169, 1910; W. Gowland, *The Metallurgy of the Non-ferrous Metals*, London, 401, 1914; C. Schnabel, *Handbuch der Metallhüttenkunde*, Berlin, **2**. 404, 1896; London, **2**. 473, 1907; A. Ditte, *L'étain et composés*, Paris, 1884; F. L. and E. Hess, *Bibliography of the Geology and Mineralogy of Tin*, Washington, 1912; W. Borchers, *Zinn, Wismuth, Antimon*, Halle (Saale), 1924.

Preliminary concentration of tin ore.[1]—Alluvial deposits of tinstone occur associated with gravel which may be more or less bonded by argillaceous matters, and covered with more or less overburden consisting of soil, clay, etc. These are worked by washing with running water, so as to break up the gravel, and carry away the lighter pebbles while the heavier tinstone is retained and recovered. The mode of washing is adapted to suit local conditions, thus, it may be done in sluices as in gold-washing. Dredging is largely used where the conditions are suitable. The *concentrates* are hand-picked to remove non-stanniferous materials; and may be re-washed in small sluice boxes, and conc. by hand jigging. Tin ore found in lodes, beds, etc.—*lode-tin, reef-tin*—in the older rocks—granite, gneiss, mica-schist, grisen, clay-slate, etc.—is associated with a comparatively large proportion, may be 95–99 per cent., of gangue consisting of earthy impurities like silica and siliceous minerals, metallic minerals like iron, copper, lead, and zinc sulphides, magnetic oxide of iron, arsenical pyrites, etc., and wolfram, a tungstate of iron and manganese of high sp. gr. closely resembling tinstone. The ore is first crushed to pass approximately a 20's screen (20 holes per linear inch), and concentrated by washing. The finely washed ore in the slimes is treated in settling tanks, or on slime tables. The tailings discharged into rivers are in some cases separated by the stream and the tinstone deposited lower down. This is recovered from time to time.

The roasting of tin ore.—The concentrates containing sulphides and arsenides and about 25–30 per cent. of tin are then roasted to remove sulphur and arsenic, and the latter is often collected as arsenic trioxide in condensing chambers attached to

the furnaces.   There are three main types of roasting furnaces, namely, (i) those like a reverberatory furnace with a fixed chamber; (ii) those with a partly movable chamber in which the charge is rabbled by the rotation of the bed below two or three fixed racks—*Brunton's calciner*—Fig. 2, or the bed may be fixed and the racks movable; and (iii) those with a movable roasting chamber usually in the form of an inclined revolving cylinder—*Oxland's calciners*, Fig. 3.   In Fig. 2, the ore is fed to the conical rotating bed A viâ the hopper B; the ore gradually works to the edge and finally lands at the discharge shoot C. The heat is supplied. D is the fire mouth.   In

Fig. 2.—Roasting Furnace with Revolving Bed.

Fig. 3, the ore is fed into the inclined revolving cylinder, A, viâ the hopper B; the ore gradually passes by gravity to the discharge C_1C_2.   The burning gases travel from the fire mouth D and are accompanied by an excess of air from openings E.   The hot gases pass from the upper part of the revolving cylinder into the condensing chambers $F_1F_2F_3F_4F_5$, where arsenic trioxide is deposited, and thence to the chimney.

The second concentration of tin ore, and the removal of tungsten.—The cassiterite and wolfram are not changed by the roasting, and the metal sulphides and arsenides
Fig. 3.—Roasting Furnace with Revolving Cylinder.

will have been converted into oxides which can be readily removed by a second washing.   Prior to washing, the roasted ore is sometimes treated in magnetic separators in which the roasted ore is carried on a series of endless belts through a strong magnetic field, when iron oxide and wolfram are deflected from the main stream of non-magnetic tinstone, etc., and delivered in separate receivers.   The tinstone is then ready for the smelter.   Details have been described by E. Walker,[2] and they are modified to suit local conditions.   The iron ore and wolfram may retain sufficient tinstone to pay for its being recrushed and returned to the magnetic separator.   If copper be present, the oxide can be removed by heating the concentrate with sulphuric acid, etc.   Iron and bismuth oxides are also removed by this treatment.

In R. Oxland's process for removing tungsten, the ore is mixed with sodium carbonate or salt-cake and heated in a reverberatory furnace; the hot mass is extracted with water to remove the soluble sodium tungstate which is recovered by evaporation.   The residual black tin is ready for the smelter.   In L. J. Michel's process, the concentrate is mixed with sodium chloride and roasted—the wolfram forms sodium tungstate; the copper, cupric chloride; the arsenic, antimony, and bismuth form volatile chlorides.   The copper is precipitated from the wash-liquor by iron; and the tungsten is precipitated as calcium tungstate by adding calcium chloride.   These processes are expensive.

The smelting of the black-tin.—The smelting [3] of the black-tin concentrate containing say 65–70 per cent. of tin depends on the reduction of stannic oxide by carbon monoxide; the reduction of the tin ore commences at about 1000°–1100°

while the metal itself melts at about 232°. Any reducible oxides also present furnish metals which alloy with the tin. Owing to the amphoteric character of the oxide, if silica be present, a tin silicate will be formed, which is not readily fusible, and if bases be present, say lime, calcium stannate will be formed. In either case, tin is lost in the slag. The use of fluorspar, lime, etc., as fluxes should be kept as low as possible to keep down the proportion of slag. As a rule, smelting works in England, Australia, France, Spain, Germany, Mexico, California, Malay Peninsula, and the Pulo Brani Island, employ a reverberatory furnace to reduce the tinstone, and shaft or blast furnaces are employed for the treatment of slags and residues. The reverberatory furnace is charged with a mixture of two to three tons of ore which is mixed with about 20 per cent. of its weight of finely divided anthracite, a little slaked lime, and maybe a little fluorspar, along with any stanniferous slag which it is desired to treat. The charge is damped with water and spread over the floor of the furnace. In about 3 hrs., the molten charge is rabbled to mix the charge and separate the metal from the slag. The temp. is then raised, the mixture is again rabbled, allowed to 'settle, and the slag raked off. The slag first pulled is usually clean enough to be thrown away, while that pulled next contains prills of tin, and is reserved for further treatment. The tin is then tapped, and cast into ingots ready for refining, or it may be partly refined before casting. A glassy liquid slag runs out after the tin. The slag left in the furnace is raked out, the furnace bottom repaired if necessary, and a new charge introduced.

Blast furnaces, however, are employed where the ore is rich and of a high degree of purity, and charcoal is used as fuel. For example, they are used at Bolivia, Billiton, Banca, Malay Peninsula, Siam, Burma, South China, Japan, Saxony, Bohemia, and Finland. Small blast furnaces of a primitive type are used by the Chinese in the Malay Peninsula. The blast furnace is first filled with charcoal, or coke, which is ignited and the blast introduced; charges of about $\frac{1}{2}$ cwt. of ore and $\frac{1}{4}$ cwt. of slag are introduced about 3 times per hour. Charcoal is introduced between each charge. The furnace is kept filled to the top, and water sprinkled on top of each charge. The tap-hole is kept open so that the charge runs out as it melts. The fore hearth is kept full of molten material, and the overflowing slag is led to a tank of water. The metal is tapped about twice in 24 hrs. Details of course vary with the local conditions, and the particular design of furnace employed.

Some advantages of the reverberatory furnace are that it enables ore of extreme fineness to be used; such an ore is obtained when the tin ore has been highly conc. Ordinary coal, producer gas, or petroleum can be used as fuel. On the average, the tin is purer than the blast furnace because a lower temp. is attained and less foreign oxides are reduced; there is also less loss by volatilization. In some cases the loss in the blast furnace is said to reach 9 per cent. The main disadvantages of the reverberatory furnace are due to the retention of tin by the refractories in the bed of the furnace; and this is recoverable only when the furnace is down for repairs. The slags are richer in tin than the blast furnace slags; and the process is intermittent. According to W. Pryce, *Mineralogia cornubiensis* (London, 282, 1778), apart from the early methods of smelting in hearths built in the ground, blast furnaces were used in Cornwall up to 1705, when reverberatory furnaces were introduced. J..Harden discussed the electro-smelting of tin ores.

The tin in slag may be present in the form of fine pills, which may be largely recovered by washing the powdered material. The tin may also be in combination. If over 5 per cent. is present, the slag may be smelted either in reverberatory or in a blast furnace. The tin so obtained is a lower grade than that first obtained. The recovery is never complete, and on an average about 6 per cent. is lost. Tin drosses consisting of tin oxide and metallic tin may be smelted with the slag or with the ore. It may be advisable first to remove the metallic tin by liquation. D. M. Levy and D. Ewan[4] have described a method of bessemerizing *hardhead* obtained in the refining of tin; and M. Guggenheim, recovered tin by volatilization in the vapour of sulphur, hydrogen sulphide, or carbon disulphide at 800°–900°.

The refining of crude tin.[5]—The purity of the metal largely depends on the purity of the ore. The ore at Banca and Billiton may yield a metal with 99·9 to 99·97 per cent. of tin and does not need refining, being, indeed, of a higher degree of purity than much of the metal obtained elsewhere by refining. When only a small proportion of impurity is present, the metal can be kept in a molten state for some time and the upper portions ladled into moulds for the market ; usually, however, the metal has to be refined since the metal obtained by the ordinary operations of smelting is contaminated with iron as the chief impurity, and smaller proportions of copper, tungsten, lead, arsenic, antimony, bismuth, etc. The process of refining involves two operations—liquation and poling, tossing, or boiling. *Liquation* is based on the fact that alloys of tin with iron, etc., are less fusible than tin. Consequently, if the impure tin be kept at a temp. just above the m.p. of tin, the tin melts and drains away while the impure metal containing ore, copper, tungsten, etc., remains in a pasty or unfused condition. The fusible compounds with lead and bismuth liquate with the tin. The phenomenon was studied by W. Kroll. In applying the process to the refining of tin, the residue in the furnace is then melted, and tapped into a float. It separates into two layers—the upper layer is impure tin, and the lower layer, consisting chiefly of tin and iron sulpharsenides, is called *hardhead*. It is used for the manufacture of tin-lead and tin-antimony alloys. The tin remaining after liquation still contains small amounts of iron, tungsten, copper, bismuth, and lead ; and it is then violently agitated so as to bring every portion into contact with air, which, in consequence of the large surface exposed, oxidizes the impurities with some tin so as to form a scoria which floats on the surface of the metal. The agitation may be effected by pouring the molten tin from a considerable height ; by *tossing* it to a series of pots ; by *poling* or boiling in which a stick of green wood is plunged beneath the surface of the molten metal, and the steam and gases which are given off bring every portion of the metal in contact with air. After the scoria has been removed, the metal is allowed to stand just above its m.p. so as to allow the less pure portions to settle. The purer upper portion is ladled into moulds as *refined tin*, and the remainder is cast as *block tin*. The bottoms, if less pure, are returned to the liquation furnace. If the molten refined tin is allowed to fall from a height, it breaks up into irregular columnar crystals, forming the so-called *grain tin ;* the same name is applied to the fragments obtained by breaking up the ingots with a mallet. T. Goldschmidt and W. Lüty removed arsenic, antimony, and copper as a scum by adding an element like sodium, calcium, zinc, or aluminium and bringing its product in contact with air or water.

The electrical smelting of tin.—According to H. Krebs,[6] tin ores become conductors of electricity at moderate temp., so that by using large pieces of ore as a resistance, sufficient heat can be developed to melt it and reduce it to metal on the addition of coal. It is not generally necessary to add any slagging material, as the ore is usually self-fluxing, nor is it necessary to protect the tin oxide from going into the slag. R. S. Wile recommended the use of a siliceous slag with a high electrical resistance. It is preferable to carry out the process in a trough furnace with a low charging shaft and two or more electrodes dipping into the bath. Ore and coal are charged in as required, and the metal is tapped from the bottom until the hearth is nearly full of slag, which should be rich in tin. The ore chute is arranged to preheat the charge, and to serve as a condenser for metal vapour rising from the smelting trough. The slag is cleaned by adding a charge of coal so as to separate its tin as metal. Although electric smelting gives satisfactory results, most tin ore is smelted as indicated above. Electric smelting is said to give a metal of a high degree of purity, and to furnish a slag with the tin content reduced as low as 0·3 per cent., while the losses by volatilization are said to be much less than by the reverberatory or shaft-furnace process. H. Herrenschmidt, and F. Mattonett discussed the smelting of tin in the electric furnace.

Electrolytic methods of refining tin.—A. Brand[7] made experiments on the refining of tin in a bath with the tin to be refined as anodes, and a soln. of stannous

chloride containing 71·84 grms. per litre, and 2·5 per cent. of conc. hydrochloric acid by vol. The tension was 0·058 volt, and 14·8 amp. ; and with 7·5 per cent. hydrochloric acid, the tension was 0·031 volt. For the deposition of a kgrm. of tin per hour, 455·6 amps. are needed, *i.e.* 26·424 watts, are consumed per kgrm. of tin ; assuming the conversion of mechanical to electrical energy involves a 12 per cent. loss, and with 25 per cent. other losses, the actual consumption of energy is given as 0·054 H.P. per kgrm. of tin. The process has not been successfully applied on a large scale. T. Rocksch precipitated crystals of tin free from spongy metal by the electrolysis of a soln. of 200 grms. stannous chloride and 2·30 grms. of 30 per cent. hydrochloric acid per litre. I. Barlot investigated the rate of deposition of tin. C. F. Claus and H. S. Sutton used sodium thiostannate as electrolyte, and the tin to be refined as anodes. The electrolyte is made by melting impure tin with an eq. amount of sulphur and soda, or sodium sulphate and carbon, and extracting the melt with water. All the impurities except antimony and arsenic are precipitated as sulphides or else collect in the anode slimes ; antimony and arsenic are precipitated with the tin on the cathode, and are then used as anodes in a bath of sodium thiosulphate and hydrochloric acid ; this removes antimony and arsenic as insoluble sulphides. In some cases an electrolyte of sodium sulphide or of alkali hydroxide is recommended. The process was recommended by S. Coles-Cowper, B. Neumann, and A. J. M. Thirot. O. Steiner electrolyzed a soln. of tin alkali sulphides ; P. Watanabe, a soln. in alkali hydroxides ; and H. Mennicke, and E. F. Kern, a soln. of tin in hydrofluoric or hydrofluosilicic acid. F. C. Mathers and B. W. Cockrum did not obtain good deposits of tin from baths containing tin salts of the mineral acids ; the best results were obtained from soln. of stannous fluoborate containing clove oil, or 0·1 per cent. of digitalin ; and from soln. of stannous perchlorate with 0·1 per cent. of phloridzin. F. Halla used soln. of the fluosilicates. E. A. C. Smith treated the ore with a gaseous reducing agent, extracted the tin with acid, and recovered the metal by electrodeposition; J. R. Stack reduced with producer gas and obtained the tin by liquation ; and E. B. Thornhill, with carbonaceous matters. R. Saxon obtained good deposits from soln. of cassiterite in soln. of alkali nitrates, sulphates, or chlorides.

The extraction of tin by wet processes.—These processes are so very costly that they offer no prospect of success commercially, although in exceptional cases —say in the preparation of tin compounds, or in preparing tin or its compounds for chemical investigations—wet processes may be used. O. J. Stannard [8] described various chemical processes of extracting tin from its ore. W. Muir dissolved the tin from the cuttings by *hydrochloric acid* and precipitated it from the soln. by means of zinc. Steam was led into the soln. during the precipitation ; milk of lime precipitated first the zinc hydroxide and then the iron hydroxide from the residual liquor. C. Künzel described an analogous process. M. Moulin and M. Dolé allowed gaseous hydrogen chloride to act on the cuttings until the iron was attacked. The products were washed out with water and precipitated from the soln. by zinc. J. J. Collins converted tin oxide in the concentrated ore into chloride. G. Lunge described the preparation of tin chloride by treating tinned plate with chlorine gas. The stannic chloride collected as a fuming liquid. A. Lambotte used a mixture of chlorine and air at 100°. T. Rondelli treated a mixture of the ore and carbonaceous matter with chlorine at 600°–800°. C. B. Schultze treated the cuttings with an acid soln. of *ferric chloride;* and the soln. was filtered through a mixture of stannous and ferric oxides until sat. If the neutralized soln. contains stannous salts, the tin can be precipitated by iron. M. G. Bachimont heated the tin ore with a *metal chloride—e.g.* ferric chloride, and the resulting tin chloride was extracted with water and precipitated by iron or electrolytically. F. von Kügelgen and H. Daneel electrolyzed a soln. of the ore in molten *sodium chloride ;* the stannic oxide was reduced to metal at the cathode. C. A. Burghardt fused the ore with *sodium hydroxide,* extracted the sodium stannate with water, and electrolyzed the soln. at 60° using sheet-iron

anodes, and tin or iron cathodes. If arsenic, antimony, or sulphur are present they should be removed by roasting before the fusion. J. Shears suggested a modification of the process. W. Borchers said that the deposition of tin oxide on the anode soon stops the current. G. Vortmann and A. Spitzer fused the ore, etc., with sodium carbonate and sulphur so as to form a soluble *sulphostannate ;* the aq. soln. was mixed with an ammonium compound and electrolyzed, using lead anodes and tinned sheet copper cathodes. W. Borchers said the losses of tin and the cost of refractories in the production of the sulphostannate are fatal to the success of the process. E. Bohne extracted tin from slags by treating the granu- lated slag with hot dil. *sulphuric acid* in lead-lined wooden boxes ; the tin was pre- cipitated electrolytically from the filtered liquid by using anodes of hardhead. H. Brandenberg and A. Weyland heated the powdered slag with a soln. of *alkali hydrosulphate,* the filtered liquor was then electrolyzed. W. O. Snelling reduced cassiterite in the presence of hydrochloric acid by using zinc as anode, and cassi- terite as cathode.

The recovery of tin from scraps of tinned plate.—This subject has been discussed by L. Hackspill,[9] G. Vié, C. E. Williams and fellow-workers, A. C. Hopper, etc. A. Gutensohn proposed scouring off the tin by a sand blast. The separation of tin from tinned plate by fusion is unsatisfactory because of the formation of an alloy of tin and iron, the adhesion of the tin to the iron, and the proneness of the tin to oxidation in consequence of the large surface exposed. L. and A. Larocque melted the tin plate admixed with finely powdered wood-charcoal and a half per cent. of sodium chloride ; R. C. Thompson melted the tin in an atm. of water-gas ; and W. L. Brockway, by the exclusion of air. J. F. Duke and F. Redman extracted the tin by melting tin-plate with lead ; and A. Harpf, and J. S. Morgan used a modification of the process. F. Wüst melted the alloy with silicon to form ferro- silicon and tin in layers. Wet methods of extracting tin have been proposed, and also for preparing tin salts from the cuttings of tin-plated sheet and from the waste waters of dye-works.

M. Moulin and M. Dolé [10] converted the tin into volatile chloride by the action of gaseous hydrogen chloride or chlorine ; the Verein chemischer Fabriken, Mannheim, used a modification of the process ; A. Lambotte, R. Lucion, G. Lunge, T. Goldschmidt, H. Mennicke, T. Rondelli, H. Davies and M. A. Adam, and F. Winteler used chlorine ; F. W. Preto,[11] S. Davis, L. Wirtz, J. W. Worsey, and C. Formenti used hydrochloric acid ; C. B. Schultze, dil. sulphuric acid ; E. Donath and F. Müllner, a dil. mixture of hydro- chloric and nitric acids ; M. Mennons, a dil. mixture of sulphuric and nitric acids ; A. Nodon, a mixture of sulphuric acid and ammonium chloride. C. J. Jakobsen [12] used alkali-lye, and others proposed to accelerate the action by the use of oxidizing agents— *e.g.* P. H. Voughan, J. M. G. Bonnet and co-workers, and J. Bang and A. Ruffin used a blast of air ; W. D. Walbridge added sodium chloride or nitrate ; F. A. Reinecken, and J. Bang and A. Ruffin, alkali nitrate ; T. Roberts and J. Dale, alkali nitrite ; E. Schunck, lead oxide or potassium chromate ; F. A. Reinecken and L. Poensgen, lead oxide ; and E. Donath, manganese dioxide. T. Twynam [13] used finely powdered coke mixed with a soln. of sodium chloride ; C. B. Schultze, and H. Davies and M. A. Adam, a soln. of ferric or stannic salts ; R. S. Wile, a 20 per cent. soln. of stannic chloride ; R. Garcia, a hot soln. of ferric chloride ; T. G. Hunter, a soln. of cupric sulphate ; A. Kissock, and E. Schunck, a boiling soln. of sodium sulphide ; and G. Vortmann and A. Spitzer heated the tin-plate with a mixture of sodium carbonate and sulphur, and precipitated the tin from aq. soln. by electrolysis.

In a number of processes, the dissolution of the tin is hastened by the aid of an electric current. J. H. Smith [14] used dil. sulphuric acid ; and A. Gutensohn, and O. Meyer dil. hydrochloric acid. J. Pusch, and P. Nauhardt recommended acid soln. in preference to an alkaline soln. Alkali-lye was recommended by J. Apitz, W. Beatson, O. Kersten, P. Keppich, E. Kotzar, A. P. Price, and L. Keith. Soln. of stannic chloride were used by C. V. Schon,[15] J. J. Collins, and P. Bergsöe ; tin salts and tartaric acid, by F. Veasey ; stannic chloride, ammonium chloride, and organic acids, by H. Mennicke ; alkali nitrate, by E. D. Kendall ; and tin sulphate and an ammonium salt, by E. Quintaine ; ferric sul- phate or a sulphuric acid soln. of sodium nitrate, by H. W. Hemingway ; ferric chloride, by J. M. Neil ; soln. of fluorine compounds, by C. Luckow. Modifications were described by P. Nauhardt, C. G. Luis, J. Pusch, H. R. S. Coleman, A. S. John, G. Cruickshank, J. Matthews and W. Davies, etc. When an alloy of tin and iron is melted with aluminium, silicon or ferrosilicon, F. Wüst found that these metals combine with the iron and liberate the tin.

Tin occurs in commerce in various grades of different degrees of purity. The block-tin from Banca and Billiton is usually of the highest degree of purity as is

illustrated by the analyses from trade catalogues [16] indicated in Table I. Analyses have been reported by T. Thomson, P. Berthier, G. J. Mulder, A. Löwe, M. von Lill,

P. G. J. Gueterbock and G. N. Nicklin, L. Addicks and W. A. Cowan, C. Himly, C. Stölzel, J. H. Baldock, C. Kopp and G. Engel, J. McKillop and T. F. Ellis, A. Stürenberg, A. Chevallier, C. L. Vlaanderen, C. M. Kersten, and numerous others. B. Kayser found mercury in a sample of commercial tin. According to F. Mylius, the purest obtainable commercial samples of tin contain 0·0013 per cent. lead, 0·0009 per cent. of iron, 0·0012 per cent. of copper, 0·0024 per cent. stannic oxide, and a trace of sulphur. Tin can be registered as *standard tin*, Class A, on the London Metal Exchange only when it assays 99·75 per cent. of tin, and is of good merchantable quality as judged by the character of a wedge-shaped piece cut from the ingot, nicked in the middle, and bent double. Table II, by

P. G. J. Gueterbock and G. N. Nicklin, gives the analyses of nine commercial brands of tin. A to F are registered as standard tin ; X to Z do not conform to this standard. G. F. Taylor [17] described the preparation of *filaments* of tin.

G. Bredig and F. Haber [18] made **colloidal tin** by passing a current at 24–72 volts through a cathode of a bright plate or wire of tin dipping in alkali-lye (1 : 2), and in conjunction with an anode of platinum. The tin is momentarily pulverized and a fine metal powder falls through the liquid. The effect does not occur with an electrolyte of dil. sulphuric or nitric acid. T. Svedberg obtained colloidal soln. of tin in organic solvents by suspending tin-foil in the solvent, and

using electrodes of iron or aluminium with a potential difference of 110 volts, and a current density so small that it can scarcely be measured by an ordinary ammeter. A second method consists in connecting a glass condenser of 225 sq. cm. surface with the induction coil and attaching the secondary poles to the electrodes, which are immersed in the liquid contained in a porcelain dish. The metal is used in a granular form or as wire chippings. When the current is passed, sparks play between the metal particles, and in the course of a few minutes dark-coloured soln. are obtained. These contain no large particles and hence need not be filtered. In the third method, T. Svedberg obtained tin in colloidal soln. by placing a piece of the metal, with its surface freed from oxide, in a flat dish ; covering it with the dispersion medium ; and submitting it to the action of intense ultra-violet rays. L. Gurvich obtained tin in a highly dispersed state by shaking small pieces of the metal with a liquid for a few hours.

The preparation of a highly purified tin.—In preparing tin of a high degree of purity for research purposes where cost of production is not of prime importance, it is usually convenient to start with Banca tin. C. T. Barfoed [19] digested the granulated metal with nitric acid ; washed the hydrated oxide with dil. hydrochloric acid, and water ; and reduced the dried oxide by heating it with sugar-charcoal ; or the hydrated oxide can be dissolved in conc. hydrochloric acid ; the soln. diluted with water ; and treated with dil. sulphuric acid. The washed product is dried, mixed with sugar-charcoal and ammonium carbonate, and heated in a porcelain crucible to redness. E. Cohen and E. Goldschmidt removed any oxide dissolved in the metal, by heating the tin in a stream of hydrogen. F. W. Schmidt dissolved the metal in conc. hydrochloric acid, and in order to remove arsenic, passed hydrogen chloride through the boiling soln. for an hour and a half. The boiling soln. was treated with sodium carbonate, and the precipitate digested with nitric acid to wash out the zinc oxide. The washed and dried precipitate was reduced with sugar-charcoal as before. E. Quintaine electrolyzed an acidified soln. of tin sulphate mixed with an ammonium salt. J. Bongartz and A. Classen recommended heating Banca tin in a current of dry chlorine to form stannic chloride ; the fraction boiling at 120° was dissolved in four times its weight of water, and treated with a conc. soln. of sodium sulphide, and sodium hydroxide eq. to about half the amount of sodium sulphide employed. The clear soln. of sodium thiostannate was electro-lyzed in a platinum dish, the tin washed with water, and alcohol ; and dried at 100°.

§ 4. The Physical Properties of Tin

The **colour** of tin is white with a slight bluish tinge. According to M. Faraday,¹ a thin film of tin in transmitted light appears to have various shades of brown ; pressing the film with an agate diminished the transmission. A. W. Wright found a thin film of tin to be brownish-grey ; and W. L. Dudley said the vapour is

blue or bluish-green. Tin has a brilliant lustre. In its lustre and whiteness tin approaches silver. The lustre depends to a large extent on the temp. at which the molten metal is poured. If the temp. is too high, the surface of the metal may show iridescent colours produced by a film of oxide; and if poured at too low a temp., the surface is dull. The presence of small quantities of foreign metals —lead, arsenic, antimony, bismuth, iron—decreases the lustre of tin, and imparts to the metal a yellowish tinge. The structure of tin is distinctly crystalline, for the cast metal is a mass of anhedral crystals. M. Volmer studied the growth of the crystals during electrodeposition. If the surface of tinned-plate or tin-foil be etched with hydrochloric acid containing a little free chlorine, or with a soln. of stannous chloride, the surface has patterns—*moiré metallique*—resembling the frost flowers on windows in frosty weather. H. Behrens found that nitric acid is not suitable for the etching; fuming hydrochloric acid is poor, and the ordinary acid acts too slowly; the best results were obtained with a mixture of fuming hydrochloric acid and potassium chlorate. The crystalline structure of tin is further evidenced by the fact noted by Geber in his *Summa perfectionis magisterii*, that when a bar of tin is bent it emits a characteristic creaking sound, called the *cry of tin*; this is supposed to be produced by the grinding of the crystals against one another during the bending of the metal.

S. Kalischer inferred that the crystalline structure is the natural form of the metal. The metal may lose this structure by mechanical working, but regains it

FIG. 4.—Structure of   FIG. 5.—Structure of   FIG. 6.—Slip-bands in
Hammered Tin.   Annealed Tin.   Crystals of Tin.

under the influence of heat. According to H. Behrens, crystalline tin which has been cast at a low temp., becomes amorphous by mechanical work; but recrystallization occurs if the metal be heated below its m.p.—say at 110° for half an hour, or a few minutes at 150°. W. Campbell obtained fine, dendritic, surface crystals by casting the metal on a surface of polished steel. G. Tammann and Q. A. Mansuri studied the temp. of recrystallization of metals. J. A. Ewing and W. Rosenhain observed that with commercial tin plate, the intercrystalline boundaries are shown by fine grooves or channels. The presence of these channels is readily accounted for by the method of manufacture, during which the plates are drawn

from a bath of molten tin and allowed to drain. The crystals of tin force any more fusible impurity to the intercrystalline junctions, and the still fluid impurities drain off, leaving a minute channel. They also found that the fine-grained structure obtained by quenching molten tin in water is not changed by exposing the metal for long periods to temp. short of the m.p. ; but a block of tin reduced to a minutely crystalline structure by severe compression recrystallizes at 150°. Fig. 4 (×33), by W. Campbell, shows the structure of hammered tin, etched with hydrochloric acid, and Fig. 5 (×16) shows the appearance of the same metal when annealed for 7 days on a hot plate at about 180°. The crystals sometimes show lines which are due to stresses set up during the rapid growth ; and Fig. 6 shows slip-bands normal to the direction of the stress. When a metal is strained beyond its elastic limit, dark lines—slip-bands—appear more or less perpendicular to the direction of the stress ; this is not due to fissuring, but is rather a result of the slipping of the components of the crystal past one another as shown by J. A. Ewing and W. Rosenhain, and by W. Campbell. The subject was investigated by O. Haase and E. Schmid. The crystallization of tin has been studied by J. Czochralsky, and W. Fraenkel, who represented his results by Fig. 7, which shows the influence of the annealing temp. and of the mechanical work on the average grain-size of the crystals. No growth of crystal grains, even after annealing, was observed during a month at 210°. A surface strained in polishing always gives a minutely crystalline structure which becomes coarser with deep etching. The deformed grains produced by tension or bending readily crystallize

FIG. 7.—The Effect of Temperature and Mechanical Work on the Grain-size of Tin.

even in boiling water. The greater the amount of cold work applied, the lower the temp. at which recrystallization sets in. The size of grain on annealing increases with the temp., and is greater the less the amount of cold work. The size of the crystals is independent of the thickness of the sheet—vide infra, hardness. W. Deutsch found the growth of crystal grains in a stressed annealed metal—tension or compression—is great, but practically zero where no stress occurs. The subject was investigated by G. Masing, and P. Ludwik. The former showed that cold-rolled tin commences to recrystallize at ordinary temp. immediately after rolling, and the grain size, after standing for 18 hrs., is approximately the same as that obtained by annealing at temp. up to 150°, and depends on the amount of rolling the tin has undergone. If the annealing is carried out at 170°–180°, secondary recrystallization, in which the smaller crystals grow at the expense of their neighbours, sets in, and the resulting metal has a very coarse crystalline structure. If it is rolled again and once more allowed to stand, then the primary crystals that form are larger than before, but of about the same size as those produced by annealing up to 150°. In this case no secondary recrystallization takes place at temp. below 150°, similar to that produced by a change in the method of working, e.g., hammering instead of rolling. The secondary crystallization following a secondary deformation is characteristic of that deformation, and does not take place if the metal, after casting, is subjected to a similar deformation without being subjected to a primary deformation. I. V. Obreimoff and L. V. Shubnikoff obtained single crystals of tin. H. Mark and co-workers found that a tin crystal elongated to a wire and heated at 150° for 3 min. is disrupted by recrystallization which begins at the ends of the wires, and grows at the rate of approximately 1 mm. per sec. The new crystal is so oriented with respect to the original that the width of the wire is not changed on elongation. If an extensible tin crystal is fractured in liquid air, in which only a low

percentage elongation occurs, non-extensible fragments are produced. M. Polanyi and E. Schmid examined the extensibility of single crystals of tin. G. Tammann and Q. A. Mansuri found that there is evidence of the coalescence of the grains of powdered tin by recrystallization at 142°. The subject was studied by M. Cook and U. R. Evans, and H. C. Burger. The **velocity of crystallization** was found by J. Czochralsky to be about 90 mm. per minute at 232°. J. A. M. van Liempt measured the heat of recrystallization, finding for 50 per cent. deformation 6·5 Cals., and for 100 per cent. deformation, 13·0 Cals.

R. J. Haüy said that the crystals of tin are *en parallélépipédes rectangulaires,* and *en aiguilles croisées ;* and J. B. L. Romé de l'Isle, *en dendrites ou en feuilles de fougère, composées d'octaèdres implantés les uns sur les autres.* In 1786, J. C. Ilsemann found that when zinc is brought in contact with a soln. of stannous chloride, the tin separates as a mass of dendritic crystals known as the *tin-tree,* or *arbor jovis.* R. Lüpke described the production of the tin-tree. J. H. Bowman found that if conc. soln. of a salt of tin is mixed with a conc. soln. of zinc chloride, glycerol, or other viscous substance, spread in a thin layer on a glass slip, and sprinkled with zinc filings, straight branched crystallites of tin are produced. The slides may be dried and the dendrites mounted in Canada balsam. P. H. Dowling found that distinct clicks occur during the cooling of tin, and these are accompanied by sudden violent deflections of an electrometer connected to the tin.

M. L. Frankenheim concluded erroneously that the crystals belong to the cubic system. W. W. Mather obtained right-angled, four-sided crystals on a piece of metal immersed in a soln. of tin chloride. Modifications of the process were used by C. F. Bucholz, A. Ditte and R. Metzner, F. Wöhler, and W. Holz. A very finely powdered tin—technically called *argentine*—is obtained by immersing a zinc or aluminium plate in a conc. soln. of stannous chloride. The argentine is used as a powder for imitating silver bronze. L. Vignon, G. Buchner, C. Goldschmidt, E. Kopp, E. Puscher, H. Harpf, and R. Jakobson have described processes for producing finely powdered tin. A. Ditte obtained crystals of tin by warming a soln. of stannous hydroxide in one of potassium hydroxide where the stannite is converted into stannate, and tin is precipitated. H. J. Brooke obtained eight-sided needles by slowly cooling molten tin until it has partially solidified, and pouring off the still liquid portion ; and L. Pajot said that he obtained rhombic plates by a similar process. A. Breithaupt reported that he had obtained short, regular, six-sided prisms from a Cornish tin furnace, but W. H. Miller said that the crystals must have been tin hemicupride, Sn_2Cu. According to W. H. Miller, when a feeble current is passed through an aq. soln. of stannous chloride, using an anode of tin, square, prismatic crystals of tin are deposited on the cathode in the course of a few days. These crystals were shown by W. H. Miller to belong to the tetragonal system, and to have the axial ratio $a : c = 1 : 0·3857$. The tetragonal crystals were obtained similarly by C. F. Rammelsberg. Modifications of the process were used by F. Stolba, A. Ssaposchnikoff, R. Zsigmondy, W. Pfannhauser, F. Schidlowsky, and F. Gelstharp. According to H. von Foullon, the tetragonal form of tin is always obtained in the reduction of tin from soln. of the chloride as indicated above. W. G. Mixter obtained the same kind of tin by placing a sodium-tin alloy, approximating Na_2Sn, in absolute alcohol, and gradually adding water ; and afterwards boiling the residue with water.

C. O. Trechmann described rhombic crystals of tin obtained from a Cornish tin furnace ; H. von Foullon obtained similar crystals from a Bohemian tin furnace ; and W. P. Headden described monoclinic crystals of stannous sulphide which were afterwards found by S. Stevanovic to be rhombic. L. J. Spencer showed that in all probability the analysis of C. O. Trechmann's product was made on a sample different from that on which the crystal constants were determined, and that the so-called crystals of rhombic tin are really crystals of stannous sulphide.

The **twinning** of the tetragonal crystals was described by W. H. Miller ; P. Gaubert showed that when tin is melted in a thin layer between two plates

of polished glass, crystals are formed which have an area of several sq. cm. when the cooling is slow enough. If the plate be punctured with a needle, a cross appears in relief on the reverse side, and several systems of parallel twins 0·5 mm. wide. Certain bands intersect at 87°, and these form a close network like that of microcline. There are also two systems intersecting at 71°, and sometimes three systems intersecting at 45°, 71°, and 64°. Bending or twisting also produces twins. The cry of tin is said to be due to this formation. H. C. H. Carpenter and C. A. Edwards, and J. Czochralsky have discussed the formation of twinned crystals during the straining of metals. O. Mügge found the twinning lamellæ above 161° indicate the crystallographic similarity of tin above and below this temp. The **corrosion figures** of tin were described by J. A. Ewing and W. Rosenhain, and H. S. Rawdon and co-workers, The corrosion figures obtained by P. Gaubert with cold hydrochloric acid are either rectangular or triangular on the original surface, but always triangular on the twinned crystals. The **X-radiogram** of tetragonal tin was examined by A. J. Bijl and N. H. Kolkmeijer, E. C. Bain, P. Niggli, M. Born and O. F. Bollnoff, G. L. Clark and co-workers, and H. Mark and co-workers. The unit prism contains three atoms in the co-ordinate positions (000), ($\frac{1}{2}0\frac{1}{2}$), and (0$\frac{1}{2}\frac{1}{2}$), and has $a=5\cdot84$ A., and $c=3\cdot16$ A., corresponding with the axial ratio $a:c=1:0\cdot406$. W. C. Phebus and F. C. Blake gave for the diamond tetragonal of white tin $a=8\cdot235$ A., and $c=1\cdot850$ A. H. Mark and M. Polanyi represented the arrangement of the atoms in the elementary ditetragonal-bipyramidal lattice by Fig. 8, where there are 4 atoms per unit. A. E. van Arkel found the lattice about half the size of that obtained by H. Mark and M. Polanyi. The effect of cold work on the X-radiogram of tin was examined by R. J. Anderson and J. T. Norton. S. Nishikawa and G. Asahara studied the X-radiograms of tin before and after heat-treatment; and M. Polanyi, after the metal had been cold-worked. The so-called rhombic tin was thought to be identical with C. O. Trechmann's rhombic tin (*vide supra*) until L. J. Spencer showed that the latter was really stannous sulphide. O. Mügge failed to detect any crystallographic change at this temp. K. Weissenberg studied the structure of the crystals; and M. L. Huggins, the **electronic structure** of tin atoms.

FIG. 8.—Arrangement of Atoms in the Space Lattice of White Tin.

C. F. Rammelsberg noted the different sp. gr. of different forms of tin—grey tin of sp. gr. 5·77–5·957, electrolytic tin of sp. gr. 6·969; and ordinary tin which has been melted of sp. gr. 7·2795; and H. von Foullon concluded from his examination of the crystalline form that tin is trimorphous—grey tin of sp. gr. 5·781–5·809; rhombic tin of sp. gr. 6·52–6·57; and tetragonal tin of sp. gr. 7·196. He regarded C. F. Rammelsberg's pre-melted tin as of doubtful significance. F. Stolba had previously shown that at about 200° tin becomes brittle enough to be pulverized in a mortar. This is usually attributed to a transformation of the tetragonal crystals into γ-tin assumed without proof to be rhombic tin; the γ-form also appears when tin cools slowly from the molten state, and it is thought that grain tin owes its peculiar structure to this modification, which, according to A. Smits and J. Spuyman, has a transition point at 200·3°. E. Janecke observed the change at 190° and 7000 atm. press. M. Werner found the heat of transformation of tetragonal to γ-tin to be 0·02 cal. per gram, and the increase in vol., 0·00017 c.c. per gram. E. Cohen and E. Goldschmidt gave for the transition temp. 195°, and later, on the strength of the observations of N. Werigin and co-workers, 175°; and later still, from the observations of P. N. Degens, 161°; M. Werner gave 161°; and A. Smits and H. L. de Leeuw, 202·8°.

Many observers have noted that ordinary tin changes into a grey powder when exposed to great cold, and medallions and coins in museums acquire a surface crust of pulverulent grey tin which gradually grows *jusqu'à la décomposition et la destruction complète*. This is the so-called *tin pest* of the museums, alluded to

by E. Babelon,[2] A. Blanchet, E. Cohen, R. Brauns, etc.   According to E. Krause,[3] there is a reference to the change, which tin undergoes when exposed to great cold, in *De mirabilibus auscultationibus* attributed to Aristotle, but more probably the work of a later writer.   In 1851, O. L. Erdmann [4] noted a structural change in the tin organ-pipes of a church at Zeitz which was thought to be an effect of vibration. C. J. Fritzsche observed that some blocks of Banca tin, after exposure to the Russian winter of 1867–8, when the temp. on January 26, 1868, was −38°, had disintegrated to granular crystalline pieces, and coarse powder.   E. Cohen cited observations to the same effect by P. Lewald, C. F. Rammelsberg, A. C. Oudemans, I. Walz, F. Petri, A. Schertel, W. Markownikoff, E. E. Emeljanoff, H. R. Richards, G. H. Englehcart, P. Hamberger, E. Hjelt, H. Hoeveler, H. Stockmeier, and K. Schaum.   W. Gowland thus referred to the change in an old vessel consisting of 94·35 per cent. Sn; 5·06 per cent. lead; 0·59 per cent. oxygen, and carbon dioxide; and traces of iron and copper :

The extraordinary mol. change which the metal of this vessel has undergone is of more interest to the physicist and metallurgist than to the antiquary.   The metal is not much oxidized, yet it is so exceedingly brittle that it can be easily broken with the fingers.   The effect of time upon it has resulted in a complete alteration of its mol. structure, the mass of the alloy being converted into an agglomeration of crystals, and to this its brittleness is due.   On smelting and casting a small fragment I found that the crystalline structure disappeared and the metal regained its original toughness.

In the tin afflicted with the disease, there are spots of a grey colour, the metal becomes brittle, and the product occupies a greater vol. than the unaffected tin. The expansion produces pustule-like excrescences at the affected centres.   This is
FIG. 9.—Surface of Tin afflicted with the Tin-pest.

illustrated by E. Cohen's photograph, Fig. 9, of a piece of infected Banca tin. The transformation travels outwards from the spots until the whole mass is infected, and the metal readily disintegrates to a brittle powder.   The disease is infectious and can be propagated by inoculation, so that if a grain of the powder be placed on a piece of sound metal, the transformation begins ; once a piece is infected, the whole mass is in danger ; the metal is " sick."   The analysis of the pulverulent grey tin is the same as that of the ordinary white metal.   In other words, grey tin, white tetragonal tin, and white rhombic tin are allotropic modifications of this element.   E. Cohen and C. van Eijk showed that the cause of the tin-pest is due to the enantiomorphic change of ordinary white tetragonal tin into the so-called *grey tin*.   If white tin be powdered, mixed with some grey tin, and kept at a low temp., say −50°, for a few days, the entire mass changes to grey tin ; and conversely, grey tin changes to white tin by warming the mass on a water-bath. Measurements of the potential difference of the two forms of tin in a cell with

stannous chloride as electrolyte, give a zero value at 18° ; at higher temp., the grey form is the positive pole, and at lower temp., the white. The transition temp. is 18°. Consequently, when the ordinary metal is kept below 18°, it is metastable, and before equilibrium can occur, it must change into the grey form. As E. Cohen and K. Inouye expressed it, white tin under ordinary conditions is in a metastable state ; but under ordinary atm. conditions, the change is exceedingly slow. The rate of change is accelerated by lowering the temp., reaching a maximum at about —50°, and thereafter diminishes as illustrated by Fig. 10. E. Jänecke observed the change through an extended interval of temp. about 20° and 600 atm. press. N. I. Stepanoff studied the rate of transformation of grey and white tin.

According to R. von Hasslinger, a tinned iron vessel, which had been kept for two years at 16°–45°, showed a crystalline, brittle surface. Other masses of tin, inoculated with small portions of the crystalline tin, underwent the same change, the area affected increasing in diameter 3–5 mm. daily. No difference between experiments at 7°, 19°, and 37° could be noted. When tin-foil was inoculated, the
FIG. 10.—Relative Speeds of Transforma-
tion of Ordinary Tin to Grey Tin at
Different Temperatures.
FIG. 11.—Equilibrium of the Allotropic
Forms of Tin (Diagrammatic).

change extended through the thickness of the foil. The crystalline tin preserves its appearance up to near the m.p., but becomes normal after melting and again solidifying. E. Cohen showed that the structural change of the worked metal consists in a recrystallization process, the result of which is the formation of larger tin crystals from smaller ones ; and that the various forms of mechanically worked tin are in a metastable condition with reference to unstrained tetragonal tin above 18°, and also with reference to grey tin below 18°. The so-called *moiré metallique*, which results when tin-plate is etched by means of hydrochloric acid and potassium chlorate, corresponds with the recrystallized tin ; and this can be used to start the change in other samples of tin-plate.

The X-radiograms of grey tin by A. J. Bijl and N. H. Kolkmeijer show that grey tin crystallizes in the cubic system, and has a space-lattice of the diamond type with the edge of unit cube $a = 6 \cdot 46$ A. The three allotropes of tin are (i) grey tin, cubic tin, or α-tin ; (ii) ordinary tin, white tin, tetragonal tin, or β-tin ; and (iii) the so-called rhombic or brittle tin, or γ-tin. According to the X-radiograms of C. von Simson, γ-tin is hexagonal. The allotropic forms of tin with their transition points are indicated in Fig. 11, where the dotted lines represent the metastable states. This is summarized in the scheme :

$$18° \qquad 161° \qquad 232°$$
$$\mathrm{Sn}_\alpha \rightleftharpoons \mathrm{Sn}_\beta \rightleftharpoons \mathrm{Sn}_\gamma \rightleftharpoons \mathrm{Sn}_{\text{liquid}}$$
O. Mügge found tin above 161° to be crystallographically the same as at ordinary temp., and S. Nishikawa and G. Asahara found no change in the X-radiogram. R. von Hasslinger, E. Cohen, and H. M. Howe examined cases where tin dulled in a certain way when pressed against bright cold-worked tin, *e.g.* tin-foil, inoculates it with a similar dullness and the infected spots thus carry the infection to others

—slowly at ordinary temp., rapidly at higher temp. This is not a case of allotropic change. The bright tin is a case of crystalline distortion produced by work; the dulled state is a state of readjustment. The phenomena is thus a case of crystalline distortion and readjustment. Cold-worked metals are in a metastable condition owing to the production of a superficial deformed layer discussed by G. T. Beilby. E. B. Wolff has also discussed the *strain disease* of tin. A. Thiel applied the term *disglomeration* to the crumbling of a reguline metal into a powder composed of small crystallites when the metal is attacked by a suitable reagent—*e.g.* tin rods which are allowed to stand in a soln. of stannous chloride which has been partially oxidized to stannic acid.

In the tenth century *The Book of the Best Things for the Knowledge of Mineral Substances* by Ahu-r-Raihan,[5] the **specific gravity** of tin is stated to be 7·31, which is near the value accepted to-day. Another Arabian writer, Al-Khazini, in his *Book on the Balance of Wisdom*, written in the twelfth century, gave 7·32 for the sp. gr. An early determination by R. Boyle gave 7·320; and D. G. Fahrenheit, 7·364 for Malacca tin, and 7·313 for English tin. D. Forbes gave 7·052 for the sp. gr. of native tin from Bolivia; it contained about 79 per cent. of tin and 20 per cent. of lead. Data have been recorded by many observers.[6] For the cast metal, J. Brisson gave 7·291; P. van Muschenbrock, 7·295; L. B. G. de Morveau, 7·2914; J. Crichton, 7·278 at 15·5°; A. T. Kupffer, 7·2911 at 17°; T. J. Herapath, 7·5565–7·600; C. J. B. Karsten, 7·2905; G. Quincke, 7·267 at 0°; O. Brill and co-workers, 7·290 at 18°/4°; H. Kopp, 7·3043; L. Playfair and J. P. Joule, 7·306 at 3·9°; W. H. Miller, 7·285–7·3043; C. F. Rammelsberg, 7·2759; J. Pohl, 7·196; R. Mallet, 7·291; E. Wiedemann, 7·25; W. Jäger and H. Diesselhorst, 7·28 at 18°; W. Gede, 7·284; E. Cohen and E. Goldschmidt, 7·287 at 15°, etc. R. Hoffmann and W. Stahl gave 7·312 at 0°/4° for 99·8 per cent. tin, and 7·311 at 20°/4° in vacuo. The best representative value for ordinary tin may be taken at 7·28 at 18°. The sp. gr. of tin obtained by metallic precipitation or by electrolysis the numbers are usually lower; thus, W. H. Miller gave 7·18; and C. F. Rammelsberg, 6·969–7·155; E. Cohen and E. Goldschmidt say that the low numbers are due to inclusions of mother-liquor with the crystals of tin. C. F. Rammelsberg gave 7·143 –7·166 for the metal reduced by hydrogen from stannous chloride, and after melting 7·310. C. J. St. C. Deville gave 7·373 for the metal slowly cooled from the liquid state, and 7·239 for the metal rapidly cooled. The sp. gr. of tin which has been hammered or rolled is usually higher. J. Brisson gave 7·299; A. Matthiessen, 7·294 at 12·8°; W. Spring found that, at 10°, unpressed tin had a sp. gr. of 7·286; after being once pressed for 3 weeks at 20,000 atm., 7·292; and twice pressed, 7·296. E. Jänecke found tin which had been repeatedly compressed had a sp. gr. 7·32. F. C. A. H. Lantsberry gave 7·231 for the sp. gr. of the annealed metal, and 7·2827 for the cold-worked metal. T. M. Lowry and R. G. Parker found the sp. gr. of tin *en masse* to be 7·2877, and for filings of the same metal 7·2784. They also found an increase in the vol. during partial annealing at 100°. G. W. A. Kahlbaum and E. Sturm found the sp. gr. of a tin rod to be 7·2932; when drawn to wire one mm. diameter, 7·2840; and when the wire was annealed for 10 mins. at 200°, 7·2840. P. G. J. Gueterbock and G. N. Nicklin measured the effect of impurities on the sp. gr. of tin. F. Paur, and F. Nies and A. Winkelmann assumed that the sp. gr. of molten tin is greater than that of solid tin because the latter floated on the former. E. Wiedemann, and W. C. Roberts-Austen and T. Wrightson, however, showed that the converse is true, the sp. gr. of the solid is less than that of liquid, and the floating is a result of convection currents in the molten metal. M. Töpler showed that tin expands 2·8 per cent. on melting, and A. Hess found a 2·5 per cent. expansion. G. Quincke gave 7·144 for the sp. gr. of the molten metal at 230°; L. Playfair and J. P. Joule gave 6·934; and W. C. Roberts-Austen and T. Wrightson, 6·974–7·025. G. Vicentini and D. Omedei gave for the sp. gr. of solid tin at 232°, 7·1835; and of molten tin at 232°, 6·988. H. Endo found a change in vol. of 2·80 per cent. during the melting of tin. C. Benedicks measured

the sp. gr. of molten tin. A. L. Day and co-workers found the sp. gr. of the molten metal to be :

	250°	300°	500°	700°	900°	1000°	1200°	1400°	1600°
Sp. gr. .	6·982	6·943	6·814	6·695	6·578	6·518	6·399	6·280	6·162

R. Arpi obtained 6·94 at 255°, 6·87 at 360°, 6·82 at 454°, and 6·76 at 536° ; and C. E. Fawsitt, 7·00 at 234°, and 6·98 at 267°. T. R. Hogness gave for the sp. gr. of tin at 302°, 6·99 ; at 319°, 6·95 ; and at 396°, 6·89 ; and he represented the sp. gr. of the molten metal at $\theta°$ by $7·01-0·00074$ $(\theta-232°)$. P. Pascal and J. Jouniaux gave 6·98 for the sp. gr. of the liquid at the m.p., 6·86 at 400° ; 6·77 at 600° ; 6·69 at 800° ; and 6·56 at 1000° ; M. Plüss, 6·967 at 280° ; and the last-named said that the sp. gr. curve has a point of inflexion at 620° in one atm. press. of an inert gas. Observations on allotropic tin were made by A. Schertel, R. H. Richards, etc. For the sp. gr. of grey tin, H. Stockmeier gave 5·8466 at 18° ; A. Wigand, 5·85 ; and E. Cohen and J. Olie, 5·751 at 18° ; and 5·768 at $-163·3°$. For white tetragonal tin, E. Cohen and J. Olie found 7·282 at 25°/4° ; and 7·350 at $-163·3°$, and calculated 7·647 at $-273°$. For rhombic tin, C. O. Trechmann gave 6·52-6·56 at 15·8°. The **specific volume** of ordinary tin at 20° was given as 0·1395 by A. Hess. K. Bornemann and P. Siebe found that the sp. vol. up to 900° is proportional to the temp. :

	409°	474°	523°	574°	602°	648°	675°	704°
Sp. vol. . .	0·1462	0·1473	0·1479	0·1486	0·1490	0·1499	0·1501	0·1506

The sp. vol. of tin computed from the observed data by A. L. Day and co-workers is indicated in Fig. 12. There is an abrupt increase of about 5·5 per cent. of the vol. of the solid at the m.p. 231·9°. J. J. van Laar calculated for b of J. D. van der Waals' equation, $b=0·00265$; for a, $\sqrt{a}=0·09$, and for the valency attraction A, $\sqrt{A}=38$. R. N. Pease, M. L. Huggins, and W. H. Bragg calculated the **atomic radius** of tin to be 1·40 A.
FIG. 12.—Specific Volume of Tin.

Tin is soft enough to be cut with a knife, but it files very badly because it chokes up the teeth of the file. Tin is softer than gold, and harder than lead. J. R. Rydberg [7] gave for the **hardness** of tin on Mohs' scale 1·8, when that of lead is 1·5, and that of gold is 2·5. S. Bottone gave for the relative hardness of tin 0·0651 when that of gold was 0·0979, and that of lead 0·0570 ; T. Turner gave 2·5 for the relative hardness of tin when that of lead was 1·0, and that of copper 8·0 ; and C. A. Edwards, 9·0 when that of copper is 53. F. Auerbach gave 11 for the absolute hardness of tin. A. Kürth, F. Sauerwald, C. A. Edwards, K. Ito, and Z. Jeffries measured the hardness of tin. F. Sauerwald and K. Knehaus gave for Brinell's hardness of tin, 40·2 at 17° ; 33·5 at 67° ; 27·5 at 117° ; 21·4 at 166° ; 16·6 at 216° ; 15·2 at 226° ; and 14·3 at 231°. K. Honda and R. Yamada measured the abrasive hardness of tin. H. J. Coe gave for Brinell's hardness of cast tin 5·2, and 5·0 for the metal annealed at 100°. Tests were also made by J. Okubo. P. Ludwik, and P. G. J. Gueterbock and G. N. Nicklin measured the hardness of tin alloyed with various proportions of various metals. P. Ludwik also measured the hardness by the indentation method, and found that it varied with temp., exhibiting a point of inflexion between 150° and 200°, as shown in Fig. 13. P. Nicolardot showed that tin is hardened by hammering. T. K. Rose found the hardness of cast tin to be 4·0-4·2 ; tin rolled at $-25°$ (ratio of thickness 8 : 1), 13·0; the same after being 30 mins. at $-20°$, 14·0 ; after 30 mins. at 0°, 13·0 ; after 1½ hrs. at 14°, 10·0-10·5; after 20 hrs. at 13°, 6·5-6·6; and 24 hrs. at

15°, 4·5 ; tin rolled at 15°, 9·5–10·0 ; the same after being 97 days at ordinary temp., 4·5 ; and after 217 days at ordinary temp., 4·2 ; after being heated to 50° and quenched, 8·6 ; and. after being heated to 100° and quenched, 5·2. These data show that the spontaneous annealing of tin occurs at ordinary atm. temp. The lower limit of annealing appears to be near 0°, for there is virtually no change after being half an hour at that temp. C. A. Edwards and M. A. Herbert gave 3·5 for the **plasticity** number when that of copper is 49·3.
FIG. 13.—Hardness of Tin at Different Temperatures.

G. Quincke [8] gave 598–681·2 mgrms. per mm. for the **surface tension** of tin ; H. Siedentopf gave 624 mgrms. per mm. in an atm. of carbon dioxide at 226° ; L. L. Grunmach, 352–359 dynes per cm. ; S. W. Smith, 480 dynes per cm. ; and W. Hagemann for the surface tension in vacuo at 247°, 539·8 dynes per cm. ; at 271°, 538·0 dynes per cm. ; at 346°, 534·8 dynes per cm. ; and at 398°, 533·9 dynes per cm. T. R. Hogness gave for the surface tension, σ, of the molten tin :

	300°	350°	400°	450°	500°
σ	526	522	518	514	510 dynes per cm.

or at $\theta°$, $\sigma = 531 - 0.080 \ (\theta - 232)$. For the **capillary constant,** a^2, H. Siedentopf gave 17·87 sq. mm. at 226° ; G. Quincke, 19·43 sq. mm. ; L. L. Grunmach, 10·87 sq. mm. ; S. W. Smith, 14·55–14·97 sq. mm. ; and W. Hagemann, 15·74 sq. mm. at 247°, and at 271° ; 15·77 sq. mm. at 346° ; and 15·83 sq. mm. at 398°. For the **internal pressure** of the solid, I. Traube gave 68,700 megabars, or 10^6 dynes per sq. cm. J. H. Hildebrand and co-workers calculated relative values for the internal press. by different methods. D. Saito and K. Hayashi measured the fluidity of the metal for casting ; and G. Subrahmanian, the **viscosity** of tin. M. von Wogau [9] gave for the coeff. of **diffusion,** k, per sq. cm. per day of tin into mercury, $k = 1.53$ at 10·7° ; and R. Kremann and A. Hrasovec made observations on this subject. W. C. Roberts-Austen found $k = 4.65$ at 500° for the diffusion of tin into gold ; and $k = 3.18$ at 500° for the diffusion of lead in tin. O. Bauer and E. Piwowarsky studied the diffusion of molten tin in solid copper.

Tin emits a peculiar smell when rubbed. This smell is not due to the metal, but to the organic substances—the fingers, for example—which come in contact with it. According to A. I. F. Levol,[10] tin is sonorous when a bar of the metal is struck. According to E. F. F. Chladni, the **velocity of sound** in tin is 2490 metres per sec. ; A. Masson gave 2640·4, and G. G. Gerosa, 2490 at 13°. J. Kleiber developed a relation between the velocity of sound, the sp. ht., and the coeff. of linear expansion of solid metals, which was applicable to tin—*vide* copper. M. Plüss found the **viscosity** of molten tin to be $\eta = 0.01678$ at 280° ; 0·01664 at 296° ; 0·01421 at 357° ; and 0·0311 at 389°. C. E. Fawsitt gave 0·0275 at 234° and 0·0235 at 267°, and these numbers are probably too high. R. Arpi gave :

	255°	308°	360°	396°	454°	507°	536°
η . .	0·0116	0·0108	0·0103	0·0100	0·0094	0·0092	0·0090

D. Saito and K. Hayashi measured the fluidity of molten tin. N. Werigin and co-workers found the relation between the temp. and the velocity at which tin could be squeezed through a small opening.

E. Jänecke found that the press. required to produce the **plastic flow** of tin through an aperture increases regularly with temp., and no discontinuity corresponding with the transformation of tetragonal into rhombic tin was observed, even after heating for a long time at 200°, and cooling slowly. The plastic flow of tin depends on its previous history, slowly cooled tin flows under a press. one-third as great as

that required to cause rapidly cooled cast tin to flow. The subject was studied by O. Haase and E. Schmid, and M. Polanyi and E. Schmid. J. Smithson found that tin could be forced through cast iron much as water can be forced by press. through gold. C. J. Burton and W. Marshall [11] found that when the press. on tin is suddenly increased to 300 atm. the temp. rises $0.277°$, and when the press. is released the temp. falls $0.264°$. W. Spring reported that by great press. clean and dry tin filings can be welded to a block (cf. 1. 13, 18).

. T. W. Richards gave for the average **compressibility** of tin at $20°$, $\beta = 1.9 \times 10^{-6}$ per megabar at 300 megabars press. L. H. Adams and co-workers gave 1.89×10^{-6} at atm. press., and 1.64×10^{-6} at 10,000 megabars press. corresponding with a 13 per cent. decrease when the press. changes from 0 to 10,000 megabars; and they represented the change in vol. which occurs between a press. p_0 and p by $-1.1 \times 10^{-4} + 1.843 \times 10^{-6}(p - p_0) + 1.27 \times 10^{-11}(p - p_0)^2$. E. Grüneisen found the compressibility of tin at $-190°$ to be 2.1×10^{-6}; and at $15.2°$, 3.1×10^{-6}. P. W. Bridgman observed the compressibility $\kappa = 1.953 \times 10^{-6}$ for extruded tin, and 1.701×10^{-6} for cast tin at $30°$; and at $75°$, 2.011×10^{-6} and 1.737×10^{-6}. He gave for the proportional change of compressibility with press., $d\kappa/\kappa dp$, respectively 0.98×10^{-5} and 0.60×10^{-5} here $d\kappa/dp = 2b$, and $\kappa = a$ in the formula for the volume change $\delta v = v(-ap + bp^2)$, where p is expressed in kgrms. per sq. cm. H. J. Coe found the press. giving critical plasticity to be 1.08 tons per sq. in. for cast tin, and 1.24–1.39 tons per sq. in. for tin annealed at $100°$. P. G. J. Gueterbock and G. N. Nicklin measured the effect of impurities on the compressibility of tin.

Tin can be rolled into very thin plates and the metal is then called *tin-foil*, or *silver-leaf*. R. Granja said that a pound of tin can be rolled 11,000 to 14,000 sq. in. The ductility of tin comes between that of copper and that of platinum. P. Nicolardot [12] showed that tin can be hardened by hammering. Tin is most ductile at a temp. in the vicinity of $100°$; and at about $200°$, it becomes so brittle that it breaks to pieces when hammered, and at that temp. it can be pulverized in a mortar. W. Rosenhain and D. Ewen found the temp. of brittle intercrystalline fracture to be $223°$ when the m.p. is $232°$.

The **tensile strength** of tin is low being about a ton per sq. in. H. J. Coe found 1.31 tons to be the maximum load of annealed tin in tension; the elastic limit was 0.1 ton per sq. in.; the elongation, 86 per cent.; and the metal was reduced to a narrow wedge. G. W. A. Kahlbaum and E. Sturm said that tin cannot be drawn into wire, but it can be rolled into that form. L. B. G. de Morveau found that tin at $100°$ can be drawn into wire, but at that temp. the metal readily breaks; a wire of 1 sq. mm. sectional area ruptured with a load of 3.5 kgrms. J. Dewar gave for the breaking stress of a rod of cast tin 0.2 in. in diameter, 200 lbs. at $15°$, and 390 lbs. at $-182°$. The elongation before breaking is about the same at $15°$ as at $-182°$. J. Dewar found that the elastic rebound of a tin sphere at $-182°$ is much greater than at $15°$. P. Ludwik, and D. H. Ingall studied the effect of temp. on the tensile strength of tin. Although flexible, the metal is elastic only within certain narrow limits. A distinct elevation of temp. occurs during repeated bending, and the metal may become so hot that it cannot well be borne by the hand; both the cry of tin—*vide supra*—and the rise of temp. are attributed to the friction of the crystals on one another. B. MacNutt and A. Concilio found that a sensitive microphone attached to a test-piece of tin in a testing machine, showed that a noise occurred in the neighbourhood of the yield-point.

G. Wertheim found the **elastic modulus** or **Young's modulus** of tin to be 4148 kgrms. per sq. mm.; W. Voigt, 5410 kgrms. per sq. mm.; H. Hess, 1700 kgrms. per sq. mm. for the cast metal, and 4100 kgrms. per sq. mm. for the rolled metal; J. Kiewiet gave 4768 kgrms. per sq. mm. for the rolled metal. The best representative value may be taken as 4500 kgrms. per sq. mm. For Young's modulus at $15°$, W. Sutherland gave 420 grms. per sq. cm. with the extremes 277–513 grms. per sq. cm. A. Mallock found the ratio of Young's modulus at $0°$ to that at $-273°$ to be 2.22. O. Faust and G. Tammann gave 3400 kgrms. per

sq. mm. for the elastic limit of tin, *i.e.* the load at which the first markings appear on a polished surface examined microscopically ; and the highest elastic limit at which the metal begins to flow freely is 5480 kgrms. per sq. mm. A. H. Stuart showed that the elastic modulus, $E = 0 \cdot 225Q$, where Q denotes the number of calories of heat per gram which would be absorbed by a rod in doubling the length under the action of heat alone. He also estimated that $Q = Dc/a$, where D denotes the sp. gr., $7 \cdot 3$; c, the sp. ht., $0 \cdot 0559$; and a, the coeff. of linear expansion, $2 \cdot 234 \times 10^5$. Hence, $Q = 1 \cdot 83 \times 10^4$ cals. ; the calculated value $E = 4 \cdot 13 \times 10^3$ agrees with the observed $4 \cdot 17 \times 10^3$ kgrms. per sq. mm. The elastic after-effect with tin was investigated by H. Shoji. W. Sutherland gave for the **rigidity** or **torsion modulus** between $0°$ and $20°$ in grms. per sq. cm. $109 \times 10^6 - 157 \times 10^6$ with the mean value 135×10^{-6} at $15°$, and for the ratio of the value at $100°$ to that at absolute zero, $0 \cdot 638$. F. Horton gave 1530 ; W. Voigt, 1730 ; and J. Kiewiet, 1543 kgrms. per sq. mm. H. Shoji found that the relation between the time t occupied in applying the stress and the torsion angle x can be represented by $x = c/t^a$, or $x = a - b \log t$, where a, a, b, and c are constants. **Poissan's ratio,** or the ratio of the lateral contraction to the longitudinal extension under the influence of a longitudinal stress, is $0 \cdot 33$. O. Faust and G. Tammann measured the elastic limit as evidenced by the appearance of slip-bands in the crystals ; W. E. Dalby, the elastic properties and plastic extension of tin ; elongation is not pro-portional to load, and contraction proceeds spon-taneously after the load is removed. R. H. Greaves and J. A. Jones found the results indicated in Fig. 14 for the notched bar **impact test** for tin. The curve falls uniformly and rapidly from $0°$ to $-100°$; and it also falls as the temp. rises from $0°$ to $190°$; after that the fall is more rapid. There is an inflection in the curve at about $16°$, and one between $160°$ and $200°$.

FIG. 14.—Impact Tests on Tin and Lead.

P. W. Bridgman, and E. von Gomperz measured the elastic properties of single crystals of tin ; and P. G. J. Gueterbock and G. N. Nicklin, the effect of impurities on the elastic properties of tin.

The coeff. of the linear **thermal expansion** of tin was found by P. S. Laplace and A. L. Lavoisier [13] to be $0 \cdot 0_4194 - 0 \cdot 0_4217$; by L. B. G. de Morveau, $0 \cdot 0_4216$; by J. K. Horner, $0 \cdot 0_4209$; by J. F. Daniell, $0 \cdot 0_4177$; by H. Kopp, $0 \cdot 0_4226$ between $12°$ and $40°$, and $0 \cdot 0_4233$ between $16°$ and $99°$; by A. Matthiessen, $0 \cdot 0_42296$ between $0°$ and $100°$; by F. C. Calvert and R. Johnson, $0 \cdot 0_42717$ between $0°$ and $100°$; and by H. Fizeau, $0 \cdot 0_42234$ at $40°$, and $0 \cdot 0_42269$ at $50°$; E. Grüneisen found the coeff. of linear expansion of tin $0 \cdot 0_42257$ between $-183°$ and $16°$, and $0 \cdot 0_42703$ between $18°$ and $100°$; P. W. Bridgman gave the proportional change of the thermal expansion, a, with press., p, to be $-da/adp = 1 \cdot 92 \times 10^{-5}$ for extruded tin, and $1 \cdot 19 \times 10^{-5}$ for cast tin. For the coeff. of the cubic expansion of tin, H. Kopp gave $0 \cdot 0_470$ between $9°$ and $72°$. G. Vincentini and D. Omodei found that the coeff. of cubical expansion of the solid metal near the m.p. is $0 \cdot 0_3114$, and that of the liquid near the m.p. $0 \cdot 0_4689$. A. Matthiessen found for the vol., v, of tin at $\theta°$ between $0°$ and $100°$, $v = v_0(1 + 0 \cdot 0000061 0\theta + 0 \cdot 00000007 89\theta^2)$. P. Glatzel found that a decimetre rod expanded $0 \cdot 002212$ mm. per degree. R. Hoffmann and W. Stahl gave $0 \cdot 0_4957$ for the coeff. of cubical expansion of tin between $0°$ and $480°$.

If the **thermal conductivity** of silver be 100, C. M. Despretz [14] found that of tin to be $31 \cdot 2$; F. C. Calvert and R. Johnson, $42 \cdot 2$; and E. Wiedemann and R. Franz, $14 \cdot 5$. In absolute units, G. Kirchhoff and G. Hausemann gave $0 \cdot 1528$ at $15°$; H. F. Weber, $0 \cdot 1446$ at $0°$; G. Wiedemann, $0 \cdot 153$ at $18°$; A. Berget, $0 \cdot 151$ at $15°$; M. O'Day, $0 \cdot 1575$ at $25°$; L. Lorenz, $0 \cdot 1528$ at $0°$, and $0 \cdot 1423$ at $100°$; and C. H. Lees, $0 \cdot 157$ at $18°$, and $0 \cdot 195$ at $-170°$; G. Glage found $0 \cdot 149$ at $35°$; and he gave $0 \cdot 378$ for what he called the temperature conductivity at $35°$. M. Jakob

gave 0·19 at −190° ; 0·155 at 0° ; 0·15 at 100° ; and 0·145 at 200°. According to S. Konno, the effect of temp. is shown by the following data :

	18°	108°	125°	209°	292°	417°	498°
Heat conductivity	0·157	0·151	0·149	0·143	0·081	0·079	0·078
	Solid.				Liquid.		

This shows that the thermal conductivity of solid tin decreases with rise of temp. up to the m.p.; there is then an abrupt fall, and the conductivity of the liquid tin decreases but slightly with rise of temp. W. B. Brown made analogous measurements and obtained 0·1428 at 50° ; 0·1404 at 102° ; and 0·1297 at 209°. E. H. Hall deduced the thermal conductivity from the electronic hypothesis. S. Laussana showed that at 1300 atm. press., the thermal conductivity of tin is 0·99 per cent. larger than its value at one atm. press.; and at 2600 atm., 1·93 per cent. larger. The average coeff. of thermal conductivity up to 2600 atm. press. was $0·0_5719$ with the press. expressed in kgrms. per sq. cm. P. W. Bridgman gave $0·0_4122$ up to 12,000 kgrms. per sq. cm. press; he also examined the thermal conductivity of single crystals.

P. L. Dulong and A. T. Petit [15] found the **specific heat** of tin to be 0·0514 ; H. V. Regnault found 0·055 between 0° and 100° ; C. C. Person, 0·05623 between 0° and 100° ; W. Jäger and H. Diesselhorst, 0·0523 at 18°, and 0·0564 at 100° ; W. Voigt, 0·0551 between 19° and 99° ; P. Schübel, 0·0556 between 18° and 100°, and 0·0582 between 18° and 200° ; R. Ewald, 0·0541 at 18°, and 0·0467 at −135° ; W. A. Tilden, 0·0577 between 15° and 180°, and 0·0499 between 15° and −182° ; H. Schimpff, 0·0556 between 17° and 100°, and 0·0488 between 17° and −190° ; U. Behn, 0·0518 between 18° and −79°, and 0·0486 between −79° and −186° ; T. W. Richards and F. G. Jackson, 0·0502 between 20° and −188° ; J. Dewar, 0·0286 between −196° and −253° ; L. Schütz, 0·0541 between 20° and −79°, and 0·0556 between 20° and 100° ; F. A. Waterman, 0·05453 between 24° and 100° ; W. Louguinine, 0·05374 at 100° ; A. Bartoli and E. Stracciati, 0·05555 between 100° and 115° referred to water at 15° ; F. Glasser, 0·055176 at 102°, 0·0562863 at 165·9°, and 0·114950 at 260° ; E. H. and E. Griffiths, 0·0536 at 0° and 0·0569 at 98° ; and C. Forch and P. Nordmeyer, 0·0530 between 14° and −190°. W. Spring gave 0·05506 between 21° and 109°, 0·05876 between 16° and 197°, and 0·05716 between 24° and 169°. He also gave for molten tin, 0·0637. J. Pionchon represented the sp. ht. of tin at $\theta°$ by $c = 0·061293 - 0·0_42094820\theta + 0·0_7163998\theta^2$; and for the sp. ht. of molten tin between 237·7°, the m.p., and 1100°, $14·375 + 0·6129\theta - 0·0_41047\theta^2 + 0·0_71034\theta^3$; and E. Béde gave $c = 0·0500 + 0·0000044\theta$ for solid tin. I. Iitaka found for solid tin, 0·0662 at the m.p., and 0·0615 for liquid tin at the same temp. ; J. Pionchon gave 0·0580 for molten tin at 250°, and 0·0758 at 1100° ; C. C. Person, 0·0637 between 250° and 350°. A. Eucken gave for liquid tin at the m.p., $C_p = 6·90$, and for the solid, $C_p = 7·0$, so that the sp. ht. of solid and liquid tin at the m.p. are nearly the same. J. N. Brönsted gave at −193° for white tin 0·0390, and for grey tin 0·0319 ; and between 0° and 20°, 0·0538 for white tin and 0·0496 for grey tin. W. H. Rodebush found J. N. Brönsted's values rather low. A. Wigand gave for white tin between 0° and 15°, 0·052, and 0·050 for grey tin. H. E. Schmitz gave 5·91 for the **atomic heat** at −85°, and 6·57 at 60° ; J. Dewar's value is 3·41 between −196° and −253°. F. Lange gave for the at. ht. of grey and white tin :

	Grey.				White.			
Abs. temp.	15·5°	31·5°	92·5°	283·7°	22·4°	56·7°	101·1°	286·3°
At. heat	0·599	1·675	4·42	6·13	1·27	4·06	5·40	6·27

E. D. Eastman made estimates of the thermal energy of the electrons in tin.

The **melting point** of tin was stated by G. A. Erman [16] to be 222·5° ; J. Crichton gave 238° ; A. T. Kupffer, 230° ; L. B. G. de Morveau, 267° ; J. F. Daniell, 228° ;

F. Rudberg, 228·5°; C. C. Person, 232·7° with an air thermometer, and 235° with a mercury thermometer; A. van Riemsdijk, 228·5°; F. Nies and A. Winkelmann, and G. Vincentini and D. Omodei, 226·5°; C. T. Heycock and F. H. Neville, 231·91°; E. Cohen and E. Goldschmidt, 231°; K. Scheel, 231·85°; H. L. Callendar, 231·9°; G. Hindrichs, 231·5°; W. R. Mott, 231·8°; E. H. Griffiths, 232·03°; L. Holborn and F. Henning, 231·83°–231·88°; L. I. Dana and P. D. Foote, 231·9°; and L. H. Adams and J. Johnston, 231·84°. C. W. Waidner and G. K. Burgess gave 231·85°–231·99° for the commercially pure metal. Numbers between 231° and 233° were found by G. J. Petrenko, A. G. C. Gwyer, R. Lorenz and D. Plumbridge, R. Vogel, N. Parravano and P. de Cesaris, W. von Lepkowsky, A. Bucher, A. Stoffel, L. Donsky, D. Mazzotto, A. P. Schleicher, K. Lewkonja, S. F. Schemtschuschny and S. W. Belynsky, F. Giolitti and G. Tavanti, E. S. Shepherd and E. Blough, E. Isaac and G. Tammann, W. J. van Heteren, D. P. Smith, P. Bogaderoff, G. Grube, N. S. Kurnakoff and N. I. Stephanoff, R. S. Williams, G. Voss, C. H. Mathewson, P. N. Degens, W. Geurtler, and W. Biltz and W. Macklenburg. A circular of the Bureau of Standards for 1919 gave 231·9° as the best representative value; and W. Guertler and M. Pirani, 232°. L. Losana represented the relative changes in the vol. of tin during melting by the curve, Fig. 15. H. Endo said that there is a 2·80 per cent. change in vol. during solidification. An increased press. raises the m.p. of tin as it does with sulphur. The rise of temp. per atm. is about +0·003275°.

FIG. 15.—The Volume Change of Tin during Melting.

G. Tammann gave for the effect of press. on the m.p., 0·00216 $(p-1)$ when the press. is expressed in kgrms. per sq. cm., or, if θ_m denotes the m.p., $d\theta_m/dp = 0·0022°$ per kgrm. per sq. cm.; and expressing the press. in atm., L. H. Adams and J. Johnston found the m.p. of tin at different press. to be:

Pressure	.	.	1	500	750	1000	1490	2000 atm.
M.p.	.	.	230·61°	232·26°	233·09°	233·89°	235·47°	237·18°

This is in agreement with the linear rule $\delta\theta = 0·003275p$. Introducing C. C. Person's datum for the latent heat (14·25 cals. per gram) and G. Vincentini and D. Omodei's for the change in vol. on melting (0·003894 c.c. per gram)., the observed value $d\theta_m/dp = 0·00328$ per atm. agrees closely with the value 0·00334 calculated from Clapeyron's equation (1. 9, 4). The result means that the m.p. of tin is raised 3·28° per 1000 atm. increased press. If the liquid phase is free to escape, so that the press. acts only on the solid phase, the m.p. is greatly lowered by the press. whether the substance expands or contracts on melting. J. Johnston showed that if Q denotes the latent heat of fusion per gramme; D, the sp. gr. at the m.p.; and T_m, the absolute m.p.; then the press, ϕ, necessary to melt a substance at the absolute temp. T is $\phi = 95·1 QD \log (T_m/T)$, and for tin, $T_m = 505°$; $Q = 14·1$; and $\phi = 2200$ atm. at 27° or 300° K. E. Jänecke verified this result. P. R. Heyl found the m.p. was raised not more than 2° when a strong electric current was passing through the metal. R. Lorenz and W. Herz studied the relation between the m.p. and the critical temp.; G. von Hevesy, the break-down of the space-lattice during melting; and W. R. Fielding, the polymerization of liquid and solid tin. P. H. Dowling observed that audible clicks occur when tin cools in a glass vessel; the phenomenon is accompanied by electrical effects and is considered to be a triboelectrical phenomenon. P. G. J. Gueterbock and G. N. Nicklin measured the effect of impurities on the m.p. of tin.

According to E. Demarçay,[17] a considerable **volatilization** of tin takes place in vacuo at 360°. A. Schuller, however, said that E. Demarçay's metal must have been impure because no perceptible volatilization was observed at a red heat in vacuo. According to F. Krafft, tin is very difficult to volatilize and in this respect approaches carbon and silicon; no appreciable volatilization occurs at 1100°

in a quartz bulb in vacuo. A. Schuller, indeed, said that tin is more difficult to volatilize than gold, but H. Moissan distilled tin at a lower temp. than gold ; and H. Moissan and A. J. P. O'Farrelley found that when an alloy of lead, tin, and copper is heated in an electric furnace, the lead and copper can be distilled off leaving the tin as a residue. For the separation of tin and lead by distillation in vacuo, *vide* lead. H. Moissan and P. Watanabe place these metals in the order of their volatility : lead, silver, copper, tin—the last being the least volatile. According to E. Tiede and F. Fischer, tin can be readily distilled when heated in the cathode-light vacuum. They found that with the purest samples of commercial tin, a deposit of tin sulphide formed on the cold walls of the glass tube, which was at first brass-yellow in colour, finally becoming dark brown to black. Pure tin, prepared from stannic chloride, did not give this deposit ; but a short exposure to the atm. of the laboratory is sufficient for some tin sulphide to be formed. W. G. Duffield measured the velocity of evaporation of molten tin. C. Zengelis considered he proved that tin can volatilize at ordinary temp. G. W. A. Kahlbaum could distil only traces of tin in vacuo at 1430° ; E. Tiede and E. Birnbräuer said that tin volatilizes at 880° in vacuo, and H. von Wartenberg that, at 2130°, tin does not volatilize rapidly enough to enable its vap. density to be measured. T. Carnelley and W. C. Williams said that the **boiling point** of tin is between 1450° and 1600° ; this is much too low. H. F. Wiebe's formula gives an equally poor result. J. J. van Laar estimated the b.p. of tin at atm. press. to be 2440°. H. C. Greenwood gave 2270° for the b.p. of tin ; J. A. M. van Liempt, 2218° ; O. Ruff and B. Bergdahl, 2270 ; and W. R. Mott, 2270°. J. J. van Laar estimated the **critical temperature** of tin to be 3730°, and the **critical pressure,** 650 atm. O. Ruff and co-workers found the **vapour pressure** of tin to be :

	2005°	2045°	2160°	2190°	2195°	2270°
Vap. press.	126	178	372	485	502	755 mm.

H. C. Greenwood gave 101 mm. at 1970° ; 262 mm. at 2100° ; and 760 mm. at 2270°. The vap. press. curve given by J. A. M. van Liempt is $\log_{10} p = -18680T^{-1} + 7\cdot5$; and for the sublimation curve, $\log_{10} p = -19050T^{-1} + 8\cdot22$. J. H. Hildebrand [18] gave for the vap. press. curve of tin, $\log p = -14444T^{-1} + 7\cdot85 + \log 4\cdot6$ mm. ; and J. Johnston, $\log p = -15100T^{-1} + 8\cdot83$, calculating the b.p. to be :

	10^{-3}	10^{-2}	10^{-1}	1	10	50	100	760 mm.
Boiling point	1010	1130	1270	1440	1660	1850	1940	2260

W. Herz studied some regularities in the vap. press. of tin and other elements. C. C. Person found for the latent **heat of fusion,** 14·252 Cals. ; F. Rudberg, 13·314 Cals. ; W. Spring, 14·651 ; D. Mazzotto, 13·617 ; J. Guinchant, 14·3 Cals. ; J. Pionchon, 14·6 ; and F. W. Robertson, 14·05 ; J. W. Richards calculated 1712 Cals. for the atomic heat of fusion. J. A. M. van Liempt gave 85·55 Cals. for the **heat of vaporization ;** and for **Trouton's constant,** 34·34. A. Henglein computed 0·132 Cal. for the mol. heat of evaporation. The atomic **entropy** of tin was calculated by G. N. Lewis and co-workers to be 11·17 Cals. per degree at 25° ; and E. D. Eastman estimated 11·5–14·1 Cals. per degree. The former obtained for grey tin 9·23 Cals. per degree.

The **refractive index,** and the **absorption index** of tin by P. Drude,[19] and G. Quincke are :

	Solid.					Molten.
γ	431	486	527	589	630	589
Refractive index	0·96	0·97	1·04	1·48	1·66	2·10
Absorption index	2·05	2·77	2·92	5·25	5·48	4·50
Reflecting power	52·3	66·5	67·8	82·5	82·2	71·9 per cent.

A. K. Aster found a refractive index 0·398 and absorption coeff. 1·46, for the molten

metal. The percentage **reflecting power,** R, of tin is indicated above.
W. W. Coblentz found :

λ	.	.	.	1·0	2·0	4·0	7·0	10·0	12·0μ
R	.	.	.	54	61	72	81	84	85 per cent.

Observations were made by E. Conroy, and F. H. de la Provostaye and E. F. Desains.
H. von Wartenberg gave 7·48 for the index of refraction for light of wave-
length 0·589μ; 5·25 for the absorption coeff.; and 8·2 for the reflecting power.
A. K. Aster found the optical properties of tin from its m.p. to 500° are independent
of the temp.   A. Ghira calculated the **atomic refraction** of tin in stannous chloride
to be 29·98 from the μ-formula, and 15·70 from the μ^2-formula; and for tin in
tin methide, 35·73; and in tin ethide, 26·36 from the μ-formula,   J. H. Glad-
stone calculated the at. refraction of tin to be 18·6–27·0.   A. Haagen found the
refraction equivalent $(\mu-1)/D$=0·1686; and the sp. refractory power 19·89.   E. van
Aubel gave 1·66 for the index of refraction of tin in its salts.   M. Faraday found
thin films of tin depolarized and rotated a ray of polarized light, as was also the case
with thin films of gold.

N. R. Campbell[20] found ordinary tin to be feebly radioactive; but not so with
the purified metal.   W. H. Bragg gave 3·37 for the stopping power of tin for the
α-**rays ;** J. Crowther gave for the absorption coeff., μ, for the β-**rays,** μ/D=9·46;
and A. S. Russell and F. Soddy for the γ-**rays** from radium, μ/D=0·281; from
uranium, 0·341; from thorium-D, 0·236; and from mesothorium, 0·305.
N. Ahmad studied the absorption of the hard γ-rays by tin.   The mean absorption
coeff., μ/D, of tin for the **X-rays** with tin as absorber :

Radiator .	.	.	Cr	Fe	Co	Ni	Cu	Zn	As	Se	Ag
μ/D	.	.	.	714	472	392	328	272	225	132	112	16

A. H. Compton studied the absorption of X-rays by tin.   D. Hurmuzesca found
the sp. absorption of the X-rays by tin is greater than with aluminium, and
smaller than with lead, iron, or silver.   C. G. Barkla and A. E. M. M. Dallas measured
the energy of the corpuscular radiation from tin bombarded by X-rays.   W. J. Rus-
sell, and R. L. Vanzetti studied the action of tin on photographic plates.
W. Ramsay and J. F. Spencer made tests on the **photoelectric action** of a number
of metals in air at atm. press., and arranged them in the order Al, Mg, Zn, Sn, Cd,
Pb. . . .; and K. Herrmann, in the order Al, Zn, Mg, Sn, Bi, Cd, Pb, . . .
G. Reboul, M. de Broglie, G. A. Dima, T. C. Sutton, and A. E. Hennings and
W. H. Kadesch examined the selective photoelectric action of tin.   T. C. Sutton
developed a relation between the photoelectric effect and the at. ht.   R. Hamer
found the limiting frequency of the photoelectric effect to be λ=3185±55.
N. Piltschikoff said that tin emits positive Moser rays.

Tin salts do not furnish a **flame spectrum** in the ordinary sense of the term.
W. F. Barrett[21] observed scarlet and green parts at the place where the hydrogen
flame comes in contact with tin.   G. Salet found that soln. of tin salts communicate
to the hydrogen flame a blue colour which was ascribed to the oxide.   Near the
centre of the flame there are two concentric rings; the inner one with a blue colour
is attributed to chlorine, with bromine the colour is green, and with iodine, yellow.
The spectrum is continuous.   The outer ring is carmine-red.   O. Schmatolla
obtained a bluish-white flame by holding a porcelain or glass rod moistened with a
conc. hydrochloric acid soln. of tin—antimony does not interfere, but arsenic does.
A. Gouy, W. N. Hartley, O. Vogel, W. von der Seipen, C. de Watteville, and
J. M. Eder and E. Valenta studied the spectrum in the oxyhydrogen and other
flames.   The **spark spectrum** of tin was examined by D. Alter, A. J. Angström,
R. Arnolds, L. de Boisbaudran, W. von Bolton, J. C. McLennan and co-workers,
M. Kimura, R. Capron, E. Demarçay, A. Ditte, J. M. Eder and E. Valenta, F. Exner
and E. Haschek, H. Finger, A. de Gramont, C. E. Gissing, A. Hagenbach and
H. Konen, F. Handke, W. N. Hartley and co-workers, W. Huggins, C. C. Hutchins

and E. L. Holden, A. Kalähne, C. Keller, H. Konen and H. Finger, G. Kirchhoff, J. N. Lockyer, A. Masson, W. A. Miller, S. R. Milner, H. W. Morse, J. Parry and E. Tucker, J. Plücker, F. R. Robinson, B. de la Roche, G. Salet, V. Schumann, R. Thalén, C. de Watteville, C. Wheatstone, J. A. Carroll, G. A. Hemsalech and A. de Gramont, etc. The most marked lines in the spark spectrum are shown in Fig. 16—the orange-yellow line 6453; the yellow line 5799; the yellowish-green line
FIG. 16.—The Spark Spectrum of Tin.

5632β; the green lines 5589, 5563, and 5331; and an indigo-blue line 4525α. The α- and β-lines are characteristic. If the spark be intensified with a Leyden jar, the lines 5589 and 5563 appear stronger than 5632 and 4525. There are a number of lines in the ultra-violet. F. Exner and E. Haschek give for the most intense lines in the spark spectrum 6452·00, 4585·80, 4524·90, 3801·32, 3262·42, 3175·15, 2863·33, and 2840·10. The arc spectrum of tin has been studied by H. Kayser and C. Runge, T. Royds, F. M. Walters, S. K. Mitra, J. C. McLennan and co-workers, H. Crew and R. Tatnall, R. Arnolds, L. Arons, O. H. Besquin, G. A. Hemsalech and A. de Gramont, R. A. Porter, F. Exner and E. Haschek, W. Gallenkamp, B. Huber, and J. M. Eder and E. Valenta. According to F. Exner and E. Haschek, the most intense lines in the arc spectrum are : 4524·90, 3801·19, 3330·80, 3262·50, 3175·16, 3034·25, 3009·33, 2863·53, and 2840·17. The *sensitiveness* of the spectral lines were studied by F. Brasack, and A. de Gramont; the *enhanced lines*, by M. Kimura and G. Nakamura, and J. Steinhausen; the influence of *self-induction*, by G. A. Hemsalech, G. Berndt, E. Néculcéa, and B. Huber; the influence of *pressure*, by W. J. Humphreys; the influence of the *intensity of the electric current*, by P. Joye; and the influence of a *magnetic field*, the **Zeeman effect,** by P. Zeeman, A. A. Michelson, P. Zonta, P. A. van der Harst, and J. E. Purvis; and the **Stark effect**, by H. Nagaoka and Y. Sugiura. The **band spectrum** was examined by A. Mitscherlich, G. Salet, G. D. Liveing and J. Dewar, W. Jevons, W. von der Seipen, R. J. Strutt, etc.; and the **absorption spectrum** of the vapour of tin was studied by J. N. Lockyer and W. C. Roberts-Austen, E. O. Hulburt, J. C. McLennan and co-workers, R. V. Zumstein, J. G. Frayne and A. W. Smith, A. L. Narayan and K. R. Rao, and W. Grotrian. The vapour exhibits a strong absorption in the blue, and a feeble one in the red. W. Grotrian found absorption lines for $\lambda = 3009·2$, 2963·4, and 2706·6 for the vapour of tin at 1050°. R. V. Zumstein studied the regularities in the spectral lines of tin. J. Formanek showed that tin salts in soln. give no absorption spectrum, and they do not react with alkanna tincture; but they do give a characteristic absorption with brásiline. J. K. Robertson studied the spectrum of tin vapour in the electrodeless discharge tube. The **ultra-violet spectrum** was studied by G. D. Liveing and J. Dewar, R. J. Lang, W. A. Miller, J. M. Eder, L. and E. Bloch, and H. Deslandres; and ' the **ultra-red spectrum**, by H. Becquerel, V. P. Lubovich and E. M. Pearen, and H. M. Randall. The **series spectrum** was investigated by P. G. Nutting, H. Sponer, P. Klein, A. Fowler, N. K. Sur and R. K. Sharma, R. Arnolds, L. Janicki, J. C. McLennan and co-workers, F. Hund, A. E. Ruark and R. L. Chenault, J. A. Carroll, and T. van Lohuizen. The last-named found six series with the variable terms given by $N/(m+1·651630-657·42\lambda^{-1})^2$, and three series with the variable terms given by $N/(m+1·384406+446·70\lambda^{-1})^2$. S. Smith studied the spectrum of electrically exploded tin wire.

P. Lewis found that the vapour of tin is not luminescent under the influence of **cathode rays.** M. Kimura and G. Nakamura [22] studied the cathodic spectrum of tin in a vacuum tube with an aluminium anode. G. Shearer studied the electronic

emission of tin under the influence of the **X-rays**; and A. C. Foley, the spectrum after exposure to ultra-violet light, and to X-rays. The high frequency spectrum or the **X-ray spectrum** of tin has been investigated by H. Kulenkampff, H. Robinson, E. C. Stoner, B. B. Ray, K. Lang, S. K. Mitra, A. Leide, B. Walter, N. Bohr and D. Coster, A. H. Compton, E. Friman, M. de Broglie, H. G. J. Moseley, etc. In the K-series, W. Duane and co-workers, A. Leide, M. Siegbahn and co-workers, K. Chamberlain, F. K. Richtmyer, S. M. J. Alleh, J. M. Cork and B. R. Stevenson found, in Angström or 10^{-8} cm. units, $a_2a'=0.49385$, $a_1a=0.48947$; and $\beta_1\beta=0.42$. D. Coster, E. Hjalmar, and M. Siegbahn gave for the L-series, $a_2a'=3.60108$; $a_1a=3.59218$; $\beta_1\beta=3.37792$; $\beta_2\gamma=3.16284$; $\gamma_1\delta=2.99493$; $\beta_4v=3.337$; and $\beta_3\phi=3.29768$. C. G. Barkla and A. E. M. M. Dallas studied the energy of the K-radiations; Y. Nishina, the L-radiations. A. H. Compton, S. J. M. Allen, F. W. Warburton and F. K. Richtmyer, studied the absorption coeff. of tin for the X-rays; E. A. Owen and co-workers, the **X-rays**; and R. Berthold, the relation between the photographic and ionizing effects of the X-ray radiation from tin. H. R. von Traubenberg found the range of the a-rays in tin is 29.4×10^{-4} cm. J. E. P. Wagstaff gave $v=2.24\times10^{12}$ for the **vibration frequency** of tin.

A. Coehn and A. Curs [23] studied the contact electricity of tin for quartz, and glass. The **electrical conductivity** of tin is about one-seventh that of silver, for A. C. Becquerel found that if the conductivity of silver is 100, that of tin is 14.01, and A. Matthiessen, 11.05. Measurements were also made by L. Weiller, F. A. Schulze, N. J. Stepanoff, H. F. Weber, H. Ihle, G. Kirchhoff and G. Hausemann, etc. J. R. Benoit gave 87,400 mhos at 0°; L. Lorenz, 93,500 mhos; A. Oberbeck and J. Bergmann gave 87,260 mhos at 0°, and 60,910 mhos at 100°; and W. Jäger and H. Diesselhorst gave 88,200 mhos at 18°, and 65,300 at 100°; J. Dewar and J. A. Fleming's results, calculated by H. Dickson, gave :

	−183°	−78°	0°	91·45°	176°
Mhos . . .	294,000	114,000	76,600	54,800	42,300

FIG. 17.—Electrical Resistance of Tin.

G. Vassura found a conductivity of 44,900 mhos of the solid at the m.p. 226·5°, and 21,100 mhos for the liquid metal at the same temp. P. Müller found 19,800 mhos at 358°, and 15,400 mhos at 860°. O. Jaamaa and Y. E. G. Leinberg measured the conductivity of powdered tin mixed with various non-conducting powders. W. von Siemens noted an abrupt decrease in the conductivity of tin during melting. E. F. Northrup and V. A. Suydam's observations on the variation of the **electrical resistance**—micro-ohms per c.c.—with *temperature* are plotted in Fig. 17. They found :

	225°	300°	400°	500°	600°	700°	750°
R . . .	22·00	49·44	52·00	54·62	57·22	59·88	61·22

Just before fusion, the resistance is 22 microhms, and just after fusion, 47·4 microhms. F. A. Schulze gave 0.0_413048 for the sp. electrical resistance of tin. J. Dewar and J. A. Fleming represented their measurements of the electrical resistance at a temp., $\theta°$, between $-100°$ and $0°$ by $R=R_0(1+0.00509\theta)$; L. Cailletet and E. Bouty, between $-85°$ and $0°$, by $R=R_0(1+0.00424\theta)$; W. Jäger and H. Diesselhorst, between 18° and 100°, $R=R_0(1+0.00465\theta)$; and G. Vicentini and D. Omodei, between 0° and 226·5°, $R=R_0(1+0.004951\theta+0.0_585544\theta^2+0.0_8350^3)$. F. A. Schulze gave for the sp. resistance of the solid at the m.p., 21.7×10^{-6}, and of the liquid 47.8×10^{-6}, and he noted no discontinuity in the curve for allotropic tin at 161°. H. K. Onnes and co-workers, and C. A. Crommelin found that the resistance of tin decreases normally with falling temp. down to $-269.2°$ or 3·8° K, and when the resistance suddenly becomes immeasurably small, the metal becomes a super-conductor. S. Smith

measured the electrical resistance of tin vapour; G. J. Sizoo and H. K. Onnes, stretching or pressure lowers the temp. at which the resistance disappears. P. W. Bridgman found the following relative values for the resistance at different temp.; and also the *pressure* coeff. of the resistance :

		0°	25°	50°	75°	100°
Resistance		1·0000	1·1080	1·2179	1·3306	1·4473
Press. coeff.	0 kgrm.	-0.0_41044	-0.0_41055	-0.0_41062	-0.0_41064	-0.0_41062
	12,000 kgrms.	-0.0_5833	-0.0_5836	-0.0_5839	-0.0_5841	-0.0_5844
	Average	-0.0_59204	-0.0_59280	-0.0_59357	-0.0_59434	-0.0_59510

B. Beckman gave -0.0_592 for the average press. coeff. at 0°, and P. W. Bridgman -0.0_41044. E. D. Williamson studied this subject. L. Grunmach and F. Weidert measured the effect of a *magnetic field* on the resistance of tin. L. Guillet and M. Ballay found the electrical resistance of tin was not increased by *cold work*. W. H. Preece found $12·8d^{1·5}$ for the current strength necessary to melt a tin wire d mm. diameter. P. G. J. Gueterbock and G. N. Nicklin measured the effect of *impurities* on the electrical conductivity of tin ; and Y. E. G. Leinberg, the electrical resistance of finely powdered tin mixed with marble, sulphur, pumice, etc. O. Jaamaa and Y. E. G. Leinberg measured the electrical conductivity of finely powdered tin. A. Stein discussed a relation between the m.p. and the electrical resistance of tin and other metals ; Z. A. Epstein, the relation of the electrical conductivity and the periodic law ; and A. T. Waterman, the theory of electrical conduction.

According to R. D. Kleeman and W. Fredrickson, tin acquires a magnetic charge when immersed in distilled water. N. A. Hesehus, showed that in a closed circuit with hot and cold tin, a current flows from the hot to the cold part. The **Seebeck effect** or **thermoelectric force** of the *iron-tin couple* was found by C. G. Knott to be $-0·001$ volt per degree difference of temp. ; and for the *lead-tin couple*, K. Noll found $-0·067$ microvolt at 50° ; and J. Dewar and J. A. Fleming, with the one junction at 0°, and the other junction at $\theta°$:

$\theta°$	100·1°	50·5°	12·4°	$-2°$	$-11·7°$	$-64°$	$-100·9°$	$-208·8°$
E.m.f.	570	340	50	0	-80	-240	-260	-440

W. Haken, and P. G. Tait measured the Seebeck effect of the tin-lead couple. For the *tin-platinum couple*, W. Jäger and E. Diesselhorst, and E. Rudolfi, gave 0·42 millivolt ; J. Dewar and J. A. Fleming, 0·45 millivolt ; K. Noll, 0·40 millivolt ; W. H. Steele, 0·41 millivolt ; H. Pélabon, 5·17 microvolts ; and E. Wagner, 0·44 millivolt. A. Smits and J. Spuyman found that with an *iron-tin couple*, the transition point of tin was indicated by a sharp break in the curve at 200·2° ; and with the *copper-tin couple*, at 200·5°. With the *tin-silver couple*, R. Räthjen found an e.m.f. of $-2·57$ microvolts. C. Benedicks found the thermoelectric force of ordinary white tin against copper to be -3 microvolts, while the value for grey tin is positive. P. W. Bridgman examined the thermoelectric force of single crystals. T. R. Harrison found for the *solid-liquid tin* couple at the m.p., 0·6 millivolt. P. H. Dowling measured the contact e.m.f. of nickel with solid and molten tin. H. K. Onnes and co-workers studied the effect of low temp. on the **Hall effect ;** and L. J. Neuman, the effect of the crystalline texture. P. Cermak found that the thermoelectric force and the **Peltier effect** with the *tin-constantin couple* does not change with the melting of the tin. E. Edlund measured the Peltier effect between copper and tin. P. Räthjen gave for the Hall coefficient, $-0·4 \times 10^{-4}$. P. W. Bridgman measured the effect of press. in kgrms. per sq. cm. on the Seebeck effect, the Peltier effect, and the **Thomson effect** with couples made with the compressed and uncompressed metals, and a selection from the results is given in Table III. M. O'Day measured the Thomson effect. Observations on the effect of temperature from $-183°$ to 93° were made by G. Borelius and F. Gunneson, who found that at $-173°$ the effect is 0·86 ; at $-143°$, 0·85 ; at $-73°$, 0·42 ; at 27°, $-0·07$; and at 137°, $-0·45$. P. W. Bridgman observed that the Seebeck effect is small and rises

to about 0.4×10^{-6} volts and reverses sign with temp. At 12,000 kgrms. per sq. cm. press., the e.m.f. passes through a negative maximum at about 25°. E. Wagner made an observation with tin, and found -0.95×10^{-6} volt at 100° and 300 kgrms. per sq. cm. press. P. W. Bridgman found that the Peltier and Thomson effects

TABLE III.—THE EFFECT OF PRESSURE ON THE SEEBECK, PELTIER, AND THOMSON EFFECT.

—	Seebeck effect. Volts $\times 10^6$.			Peltier effect. Joules per coulomb $\times 10^6$.			Thomson effect. Joules per coulomb $\times 10^6$.		
Temp.	Press. kgrms. per sq. cm.			Press. kgrms. per sq. cm.			Press. kgrms. per sq. cm.		
	2000	6000	12000	2000	6000	12000	2000	6000	12000
0°	40·001	−0·014	−0·136	0	−0·66	−4·92	−0·3	+5·9	+29·9
40°	0·024	+0·042	−0·081	+0·41	+1·06	+2·68	+0·6	+3·0	+6·6
60°	0·052	0·111	+0·103	0·43	1·13	3·03	−0·5	−0·7	−2·0
100°	0·087	0·165	0·390	0·11	0·90	1·75	−1·1	−2·0	−5·0

change sign. At low temp., the Peltier effect is negative, i.e. heat is absorbed by the positive current in flowing from the compressed to the uncompressed metal across the junction, but at higher temp. the effect of all press. is to make the effect positive. It then passes through a maximum and decreases again. The Thomson effect is initially positive for low temp., and becomes negative at higher temp.

The **Volta difference of potential** of two metals in contact in air varies with the condition of the metal surface, and the nature of the surrounding atm. W. E. Ayrton and J. Perry [24] gave for ordinary commercial metals at 18°, in volts :

	C	Pt	Cu	Brass	Fe	Pb	Zn	Zn-Hg
Sn . .	−0·795	−0·690	−0·456	−0·372	−0·313	0·099	0·281	0·463

W. Hankel, F. Exner and J. Tuma, and H. Pellat made observations on this subject. A. Volta, J. W. Ritter, J. C. Poggendorff, T. Seebeck, J. C. E. Péclet, P. S. Munk, J. M. Gaugain, and C. H. Pfaff placed tin near the middle of the **electrochemical series :**

K, Ba, Mg, Al, Mn, Zn, Cd, Fe, Co, Ni, **Sn,** Pb, H, Cu, Bi, Sb, Hg, Ag, Pd, Pt, Au.

A. Coehn and A. Lotz found tin to be electronegative towards glass. G. T. Fechner measured the series obtained using water, and a soln. of sodium chloride as electrolytes ; H. Davy, M. Faraday, and J. C. Poggendorff, dil. sulphuric acid ; A. de la Rive, M. Faraday, and S. Avogadro and V. Michelotti, dil. and conc. nitric acid ; M. Faraday, hydrochloric acid ; P. Marianini, sea-water ; J. C. Poggendorff, soln. of ammonium chloride, potassium cyanide, and potassium ferrocyanide ; and H. Davy, and M. Faraday, soln. of potassium hydroxide and sulphide. F. W. Bergstrom found the electrochemical series in liquid ammonia : Pb, Bi, Sn, Sb, As, P, Te, Se, S, I.

A. Naccari and M. Bellati found for carbon and tin in an aq. soln. of chromic acid, 67·0 when the e.m.f. of a normal Daniell's cell is taken as 100 ; C. Hocken and H. A. Taylor observed 0·571–0·626 volt with the zinc-tin couple in dil. sulphuric acid ; and 0·509–0·531 volt in a conc. soln. of zinc sulphate. A. Oberbeck and J. Edler observed the effect with the mercury-tin couple in soln. of the hydroxides, carbonates, nitrates, chlorides, bromides, iodides, and sulphates of potassium, sodium, zinc, and cadmium, and with sulphuric, nitric, and hydrochloric acids, and with aq. ammonia.

According to C. M. van Deventer, owing to the formation of a layer of a badly conducting salt, tin may become cathodic to lead in a mixture of alcohol and water. P. H. Dowling found that there is no contact e.m.f. between liquid and solid tin.

E. Newbery found that in acid electrolyte, tin shows no signs of **passivity,** but readily becomes passive in alkali-lye. At the same time, a black coating is formed similar to that obtained with zinc. The nature of these black substances is under investigation. The electrical resistance of the coating is considerable, since an applied electromotive force of 8 volts only produced a current of 0·4 ampere per c.c. The over-voltage rises to a very high value, and is very erratic. The apparent over-voltage is probably raised artificially to some extent by the action of the badly conducting coating forming a small capacity condenser which is charged by the primary exciting current and then discharged through the potentiometer. The passivity and the **polarization** of tin were investigated by C. F. Bucholz, J. W. Ritter, G. T. Fechner, C. F. Schönbein, C. Wetzlar, M. Eckardt and H. Goldschmidt, F. Förster and M. Dolch, G. C. Schmidt, M. Dresbach and H. R. Hosmer, and R. Steinherz. According to V. Rothmund, tin becomes passive in soln. of sulphuric, hydrofluosilicic, and the halogen acids, but not in nitric, iodic, perchloric, or acetic acid. The metal goes into soln. to form stannous salts from both the active and passive states. The **over-voltage** of tin was examined by F. Meunier, and W. D. Harkins and H. S. Adams. C. Hambuechen gave 0·55 volt for the over-voltage of hydrogen on tin ; and A. Thiel and W. Hammerschmidt, 0·401 for 0·01N-H_2SO_3. H. von Steinwehr calculated $1·3 \times 10^{-5}$ atm. for the **electrolytic solution pressure** of tin Sn→Sn″.

N. T. M. Wilsmore measured the **electrode potential** of tin referred to the hydrogen electrode and found less than 0·192 volt ; A. A. Noyes and K. Toabe gave 0·146 volt. B. Neumann found the potential of tin against a soln. of stannous chloride to be —0·985 volt ; A. Fischer found the potential against a 2N-$(NH_4)_2S$ to be —0·244 volt ; ($\frac{1}{13}N$-Sn) soln. of $(NH_4)_2SnS_3$, —0·237 volt ; sat. soln. $(NH_4)_2SnS_2$, —0·263 volt ; N-NaSH, —0·545 volt ; ($\frac{1}{15}N$-Sn) soln. of Na_2SnS_3, —0·598 volt ; N-Na_2S, —0·610 volt ; 3N-Na_2S, —0·620 volt ; and N-NaOH, —0·654 volt. E. Müller found the potential difference required to produce the smallest visible quantity of hydrogen from normal sulphuric acid to be 0·43 volt. G. Tammann measured the potential of tin against fused cuprous and silver chlorides. N. R. Dhar studied some anomalies in the electrochemical behaviour of tin ; and M. Schlötter, the electrodeposition of tin.

G. Magnanini measured the potential difference in centi-volts between zinc in a normal soln. of sulphuric acid, and tin placed in the given soln. of the molar conc. —M mols per litre—named :

0·5M-H_2SO_4, 51·3 ; M-NaOH, 0·2 ; M-KOH, —1·2 ; 0·5M-Na_2SO_4, 51·4 ; M-$Na_2S_2O_3$, 45·7 ; M-KNO_3, 31·1 ; M-$NaNO_3$, 40·9 ; 0·5M-K_2CrO_4, 40·9 ; 0·5M-$K_2Cr_2O_7$, 68·1 ; 0·5M-K_2SO_4, 40·9 ; 0·5M-$(NH_4)_2SO_4$, 57·6 ; 0·25M-K_4FeCy_6, 41·2 ; 0·334M-K_3FeCy_6, 130·9 ; M-KCyS, 52·7 ; 0·5M-$Sr(NO_3)_2$, 48·7 ; 0·125M-$Ba(NO_3)_2$, 52·8 ; 0·2M-$KClO_3$, 57·7 ; 0·167M-$KBrO_3$, 50·9 ; M-NH_4Cl, 50·9 ; M-KF, 50·8 ; M-NaCl, 50·3 ; M-KBr, 52·5 ; M-KCl, 52·6 ; 0·5M-Na_2SO_3, 31·0 ; M-NaOBr, 70·6 ; M-$C_4H_6O_6$, 54·4 ; 0·5M-$C_4H_6O_6$, 57·6 ; 0·5M-$C_4H_4KNaO_6$, 42 to 47. Measurements for a number of salts were also made by E. F. Herroun, and by C. R. A. Wright and C. Thompson.

O. Sackur gave —0·440 volt for the **electromotive force** of a cell with Sn | 0·05N-$Sn(CO_3)_2$ | 0·5KNO_3 | N-KCl against a calomel electrode at 25° ; N. R. Dhar, Sn | $NaCl_{soln.}$ | KCl | 0·1N-calomel electrode, etc.

F. Förster and J. Yamasaki found with a normal calomel electrode against Sn | 0·897N-$SnCl_2$ | sat. KCl | N-KCl, —0·471 volt at 18·5°–19° ; against Sn | 0·092N-$SnCl_2$ | sat. KCl | N-KCl, —0·480 volt at 18·5°–19° ; Sn | 0·492N-$SnSO_4$ | sat. KCl | N-KCl, —0·473 volt at 18° ; against Sn | 0·010N-$SnSO_4$ sat. KCl | N-KCl, —0·494 at 18° ; against Pt | 0·45$SnCl_2$, 0·05N-$SnCl_4$, N-NH_4Cl | sat. KCl | N-KCl, 0·181 volt at 18° ; against Pt | 0·05N-$SnCl_2$, 0·45N-$SnCl_4$, N-NH_4Cl | sat. KCl | N-KCl, —0·122 volt at 18° ; and for the cell Pt | 0·45$SnCl_2$, 0·05N-$SnCl_4$, 0·5N-HCl | sat. NH_4NO_3 | 0·5N-H_2SO_4, solid Hg_2SO_4 | Hg, 0·552 volt at 18° ; and Pt | 0·05N-$SnCl_2$, 0·45$SnCl_4$, 0·5N-HCl | sat. NH_4NO_3 | 0·5N-H_2SO_4, Hg_2SO_4 solid | Hg, —0·506 volt at 18°.

W. Ostwald gave 20 Cals. for the **heat of ionization** of Sn″-ions from the element tin ; A. Günther-Schulze [25] observed no **electrolytic valve action** with

tin; but W. Winter observed a strong anodic valve action with potash-lye. G. von Hevesy and R. Lorenz found the **electrocapillary phenomenon** with the system Sn : LiCl, KCl resembled that with the ordinary mercury-sulphuric acid electrometer. According to J. Smrz, tin is deposited reversibly on the dropping cathode from freshly prepared acidic soln. of stannous chloride, the normal deposition potential being -0.285 volt relative to the calomel electrode. From freshly-prepared alkali stannite soln., tin is deposited reversibly; a $4 \times 10^{-4}M$ stannite soln. deposits tin at -1.10 and -1.05 volts from N- and $0.1N$-sodium hydroxide soln., respectively. These soln. are unstable owing to the gradual formation of colloidal stannous hydroxide and to partial auto-oxidation of stannite to stannate. In normal sodium hydroxide soln., the solubility product $[\mathrm{Sn}^{..}][\mathrm{OH}']^2 =$ about 10^{-28}; the acidic solubility product of stannous hydroxide, $[\mathrm{SnO_2H}'][\mathrm{H}^{.}] = 6 \times 10^{-13}$; the constant for the formation of the complex anion $K_A = [\mathrm{Sn(OH)}'_3]/[\mathrm{Sn}^{..}][\mathrm{OH}']^3 = 4 \times 10^{24}$. Of the hydroxides of lead, zinc, and tin, lead hydroxide is the strongest and stannous hydroxide the weakest, the acidic order being the reverse. The **electric discharge** between tin electrodes has been studied by F. Fischer and co-workers, V. L. Christler, V. Kohlschütter and co-workers, and F. Müller; and the spluttering of the tin cathode, by W. Crookes. F. Fischer and G. Iliovici examined the spluttering of tin in liquid argon. For spluttering under water, etc., *vide* colloidal tin. According to R. D. Kleeman and W. Fredrickson, if an electric current be passed through water in which a rod of tin and one of carbon are immersed, the metal acquires a negative charge.

Tin is paramagnetic. For the **magnetic susceptibility** A. P. Wills [26] gave $+0.35 \times 10^{-6}$ vol. units; M. Owen, $+0.02 \times 10^{-6}$ mass units; and O. C. Clifford, $+0.31 \times 10^{-6}$ mass units. K. Honda gave $+0.03 \times 10^{-6}$ mass units at $18°-240°$, for white tin, and -0.4×10^{-6} mass units at $18°$ for grey tin. M. Owen also gave -0.255×10^{-6} mass units for grey tin. For liquid tin, K. Honda gave -0.04×10^{-6} mass units over $240°$. The magnetic susceptibility of a number of tin salts has been determined by P. Pascal, A. Dauvillier, S. Meyer, G. Quincke, and C. Chéneveau; the magnetic moment of tin by W. Gerlach and A. C. Alliers.

§ 5. The Chemical Properties of Tin

Tin is chemically related to silicon, titanium, zirconium, germanium, and cerium. The metal is not affected, chemically, by **hydrogen**; and L. L. Bircumshaw [1]

found that absorption of hydrogen by tin at about 800° can be represented by $w = 3\cdot38 - 2\cdot86e^{-0\cdot0074} - 0\cdot52e^{-0\cdot0666t}$, where w represents the amount of gas dissolved at the time t. F. H. Newman found that with tin electrodes in an electric discharge tube nitrogen, but not hydrogen, is absorbed. C. W. G. Kastner said that a **tin hydride** can be prepared, but E. Voegelen's attempts to make such a compound were nugatory. On the other hand, there are numerous alkyl derivatives of tin tetrahydride, or *tin-methane*. D. P. Smith, and F. Paneth have shown that the position of tin in the periodic table is not incompatible with the formation of a hydride. F. Paneth and K. Fürth found that when the gas, obtained by the action of $4N$-hydrochloric or sulphuric acid, is passed through cotton-wool, dried by calcium chloride and phosphoric anhydride, and led through a heated hard-glass tube, a mirror of metallic tin is formed in close proximity to the hot part of the tube, which, when well developed, consists of three zones, a whitish-grey, blackish-grey to black, and finally brown in colour. The reactions of the mirror are characteristic of tin, the most distinctive of them being the insolubility in cold, conc. nitric acid ; and the formation of purple of Cassius and calomel by gold and mercuric chlorides, respectively, after a pre-liminary treatment of the ring with dry, gaseous hydrogen chloride. The gas can be condensed by liquid air and re-evaporated without decomposition. The yields, however, by these processes are poor—only a few thousandths per cent. of the tin of the alloy are converted into the hydride. W. Vaubel said that the compound Ag_4Sn is produced by the action of tin hydride on soln. of silver nitrate. He also found that a 5 per cent. soln. of acetic acid, or a 1 per cent. soln. of oxalic acid, acts on tin-plate containing rusty spots, or with iron in contact with tin, producing tin hydride ; and added that the formation of tin hydride in soln. may account for cases of poisoning by eating food from tins showing rusty spots. E. J. Weeks obtained this hydride by the action of hydrogen on tin dihydride. F. Paneth and E. Rabinovitsch prepared tin hydride by the electrolysis of a soln. of tin sulphate between tin or lead electrodes. The presence of a small proportion of colloids—*e.g.* 0·5 per cent. of dextrin, gelatin, gum arabic, or agar-agar—or of certain crystalloids—*e.g.* sugar—greatly increases the yield, and also stabilizes it.

Electrolysis is effected conveniently in a crystallizing dish or beaker, in which the anode, made of lead rod, is placed in a small, porous cell. The cathode is formed by melting lead in a curved glass tube, through one end of which a copper wire is inserted into the metal while hot ; the metal at the other end of the tube is affixed to a lead disc. The junction between metal and glass is rendered liquid-tight by gypsum or paraffin. The cathode is placed under a small bell. This form of cathode has the advantage that it may be removed without disturbing the remainder of the apparatus. The cathode requires a preliminary treatment so as to cover it with a loose, black deposit of the spongy metal. Zinc, mercury, or amalgamated zinc or lead are not suited for cathodes, but lead, tin, cadmium, or platinum can be used. The current density employed is 0·5–7·5 amps. per sq. cm. The tin hydride is washed by water and alkaline lead acetate soln., dried by passage through tubes at −80° to −100° and condensed by liquid air. It can be further purified by fractional distillation and condensation.

The analysis agrees with SnH_4, and no indications of other tin hydrides were observed. Tin hydride has a m.p. of −150° ; its vap. press. is log p $= -1000T^{-1} + 7\cdot4$; the latent heat of evaporation is 4·55 Cals. Tin hydride is fairly stable. It decomposes spontaneously in a few days when kept in glass vessels, but the change is not accelerated by light. The gas decomposes immediately at 145°–150°. The mirror obtained from the purified gas is generally pale grey or silvery ; and it is formed in front of or in the heated part of the tube. The brown mirrors obtained with the impure gas are those of tin sulphide. Tin hydride is very sensitive to the nature of the surface with which it is in contact. The instability of the gas in contact with solid desiccating agents (calcium chloride, phosphoric oxide) is probably a manifestation of this phenomenon. It is unaffected by dil. alkali hydroxide soln. (up to 15 per cent.), dil. sulphuric acid, dil. and conc. nitric acid, and most metallic salts (sodium carbonate, copper sulphate, lead acetate, ferric

chloride); it is absorbed to some extent by conc. alkali hydroxide soln. or by conc. sulphuric acid, completely by solid alkali hydroxide and soda-lime. It is quantitatively absorbed by silver nitrate (or sulphate) soln., giving a black precipitate which contains silver and tin in varying proportions, whilst tin is also present in the soln. It appears to reduce mercuric chloride to mercurous chloride. E. J. Weeks prepared **tin dihydride**, Sn_2H_2, by adding aluminium foil to an alkaline soln. of potassium stannite: $2KHSnO_2+2Al=2KAlO_2+Sn_2H_2$. The dihydride quickly oxidizes in air, and when heated, forms tin and water; with fused potassium nitrate, it forms nitrogen peroxide: $Sn_2H_2+5KNO_3=KNO_2+H_2O+2K_2SnO_2+4NO_2$.

B. Delachanal found that tin occludes some gases, for, by heating 1000 grms. of tin in an evacuated porcelain tube, he obtained a mixture containing 3·25 c.c. of hydrogen, 2·80 c.c. of methane, 2·05 c.c. of carbon monoxide, 1·94 c.c. of carbon dioxide, and 1·56 c.c. of nitrogen. It was assumed that the methane was produced by a reaction between the hydrogen and carbon monoxide. A. Sieverts and co-workers observed no evidence of the dissolution of hydrogen by molten tin. F. Fischer and G. Iliovici obtained no sign of a combination of tin with argon when an electric arc between tin electrodes, was formed beneath liquid **argon**. F. H. Newman studied the adsorption of gases by tin in the electric discharge tube. Tin is but a little affected by **air** at ordinary temp. even in the presence of moisture. Consequently, tin is much used in the form of tinned iron—tin-plate—for culinary utensils, etc. The metal seems to acquire a superficial pellicle of oxide which protects it from further action. G. Tammann[2] estimated that the metal in dry air would take 36×10^8 years to form the first visible layer of oxide. L. Vignon found that the metal precipitated by zinc from stannous chloride, when washed and dried in air appears to be infusible. It is really a mixture of 22·5–33·4 per cent. of stannous oxide and tin. The latter can be separated by liquation. The precipitated tin is partly converted to stannous oxide during the drying, and the oxidation takes place the more readily, the less the proportion of free acid present in the liquid from which the tin was precipitated; if much free acid is present, the tin does not oxidize during the drying. G. Buchner said that tin which has been precipitated by zinc or aluminium from alkaline soln. is more stable than tin derived from acidic soln. These differences are probably due to variations in the grain-size of the pulverulent metal. L. Vignon said that if tin be cleaned by dipping in molten zinc chloride; exposed to moist air for a month; and again treated with zinc chloride, it loses weight, probably owing to oxidation. C. O. Bannister found that the corrosion product of a specimen of old tin—99·98 per cent. Sn—contained: hydrated stannous oxide, 43·35 per cent.; SnO_2, 54·68; CuO, 0·81; SO_3, 0·85; Fe_2O_3, etc., 0·12; and CaO, 0·10. S. Kappel found that when tin is warmed in contact with ammonia or alkalies, and in a stream of purified air, some hydrogen dioxide is formed.

The production of stannic oxide by heating tin in air or **oxygen** was discussed in connection with stannic oxide. A. P. Bolley said that when the metal is heated to near its b.p., it burns in air with a pale white flame. According to L. Vignon, finely-divided tin precipitated by zinc from a dil. soln. of stannous chloride, washed, and dried, in air, burns like tinder when heated in air at a temp. below the m.p. of the metal. Powdered tin, obtained by agitating the melted metal in a wooden box, contains stannous oxide, and when heated with resin, borax, or any other substance which is commonly used as a flux for soldering, the metal becomes readily fusible. Zinc chloride soln. has no effect, but the fused salt simply dissolves the stannous oxide; ammonium chloride forms stannous chloride with liberation of ammonia; resin reduces the stannous oxide to metal. E. Jordis and W. Rosenhaupt said that tin darkens in colour when heated to 145° in dry oxygen for a long time, but the amount oxidized in very small—38·727 grms. consumed a c.c. of oxygen in 264 hrs. Moist oxygen acts more quickly. G. C. Schmidt found very little change in the potential of tin when oxygen or hydrogen is passed over

the metal. According to F. Emich, when pure block tin is heated in a stream of air or in an open porcelain crucible, drops of molten metal ooze after some hours from beneath the superficial crust of stannic oxide, and, becoming superficially oxidized, gradually assume curious globular and vermiculitic forms, recalling Pharaoh's serpents. If tin containing 0·5 per cent. of iron be treated similarly, most of the iron is eliminated with the first portions of stannic oxide, a mere trace (0·001 per cent.) being left in the tin. The stannic oxide assumes a colour varying from brown to yellow with the amount of iron, thus serving as a good qualitative test for that impurity. The oxide formed after the iron has been eliminated is snow-white. W. Manchot found that air containing one per cent. of ozone acts on molten tin at 500°. M. Traube, and R. Wolfenstein showed that tin is not oxidized by a soln. of **hydrogen dioxide,** nor is the latter decomposed catalytically by the tin.

H. Fleck [3] reported the presence of traces of tin in **water** which had been distilled through a still-head and condensing worm of that metal; he added that the action of cold water is very slight, but hot water acts a little faster. The action of water on tin and lead was discussed by M. E. Chevreul. M. Traube-Mengarini and A. Scala said that in contact with distilled water, tin furnishes a colloidal sol, and that the minute particles can be detected by the ultramicroscope. J. L. Gay Lussac, and H. V. Regnault found that steam is decomposed by red-hot tin, forming stannic oxide. W. G. Whitman and R. P. Russell examined the effect of oxygen dissolved in acids on the corrosion of tin. **Salt solutions** act on tin more quickly than does water alone. A. Claudius, and A. W. Lindes showed that warm aq. soln. of *ammonium chloride, sodium chloride, potassium hydrosulphate,* and *potassium aluminium sulphate* dissolve tin, but soln. of *sodium nitrate, potassium nitrate, sodium tetraborate,* and *sodium hydrosulphate* have very little action. Soln. of *potassium carbonate, sodium sulphate, calcium chloride, barium chloride,* and *magnesium sulphate* act in the presence of air, forming stannic oxide. K. K. Järvinen studied the attack of tin by sodium chloride soln. E. J. Hallock said that conc. soln. of sodium or calcium chloride and *ammonium nitrate* readily attack tin, while soln. of ammonium chloride have very little action. A. Wagner said that in the presence of air freed from carbon dioxide, sodium carbonate has but little action on tin; and alkali chlorides, ammonium chloride, magnesium chloride, and *potassium sulphate* have still less action; while distilled water, and lime-water have no action at all. E. Cohen found tin to be attacked by sea-water and atm. air. A. J. Hale and H. S. Foster found that $\frac{1}{5}N$-soln. of magnesium chloride, calcium chloride, and sodium chloride at 17°–20° dissolved per sq. dcm. of metal respectively 0·16, 0·13, and 0·00 grm. per day during 7 days; and 0·10, 0·08, and 0·08 grm. per day during 28 days. A $\frac{1}{5}N$-sodium carbonate soln. had no appreciable action during 28 days. C. Reichelt said that water containing sodium chloride oxidizes tin more readily than water alone, but no tin is dissolved. S. P. Sharples found a block-tin tank was "riddled by corrosion" and coated with oxide by water free from nitrates but containing a little calcium sulphate and sodium chloride. A. M. Knight also gave a similar example. Soln. of *alkali hydroxides* dissolve tin very slowly, forming alkali stannates, and, as indicated in connection with the wet process for stripping tin from tin-plate, the action is accelerated in the presence of air, or of oxidizing agents. O. P. Watts and N. D. Whipple found that with 190 c.c. of N-sodium hydroxide at 37·5° for 45 hrs., 0·0005 grm. per sq. cm. was dissolved from tin; and when 0·25 grm. sodium arsenate, 10 grms. potassium permanganate, or 10 grms. potassium nitrate, were added per 190 c.c. of the alkali-lye, then 0·0005, 0·00113, or 0·0005 grm. of tin per sq. cm. was respectively dissolved; with a soln. of 200 grms. of sodium hydroxide per litre, and 5 grms. of picric acid per 180 c.c., 0·0622 grm. of tin per sq. cm. was dissolved in 45 hrs. at 46°; and with tin amalgam, SnHg, and the same alkali soln. with and without the picric acid, 0·00512 and 0·00001 grm. per sq. cm. was respectively dissolved. A. J. Hale and H. S. Foster found that $\frac{1}{5}N$-NaOH at 17°–20° dissolved tin at the rate of 0·30 grm. per sq. dcm. per day during 7 days, and 0·50 grm. per

sq. dcm. per day during 28 days. According to K. Elbs and H. Thümmel, a tin anode dissolves in soln. of sodium chloride or sulphate, or in hydrochloric or sulphuric acid, almost entirely in the stannous condition. For the action of soln. of *alkali sulphides,* and the anodic dissolution of tin in soln. of alkali hydroxides or alkali sulphides, *vide* wet processes for stripping tin-plate, similarly also for the action of soln. of ferric salts, stannic salts, and of copper salts. Objects made of tin have been reported from old pile-dwellings in a good state of preservation ; but they are also found encrusted with white or brown layers of hydrated stannic oxide ; and sometimes the oxidation has advanced so far that no trace of metallic tin remains. The corrosion of tin by various reagents was discussed by H. F. Whittaker ; by acidic mine-waters, by R. E. Hall and W. H. Teaque ; and by photographic soln., by J. I. Crabtree and co-workers.

The halogens unite directly with tin, forming stannic salts. H. Moissan [4] said that **fluorine** does not react with tin at low temp., but at 100° it forms stannic fluoride. Dried **chlorine** and **bromine** were found by R. Cowper, and R. Lorenz to act on tin at ordinary temp. E. Beckmann and P. Geib also found that liquid chlorine attacks tin. J. L. Gay Lussac found that **iodine** at 50° unites directly with tin. In agreement with the thermal values of the reaction, said M. Berthelot, tin is easily attacked by **hydrogen iodide** and **hydrogen bromide,** and less readily by **hydrogen chloride.** Tin is feebly attacked by **hydrofluoric acid,** and is slowly dissolved by dil. **hydrochloric acid ;** with hot, conc. hydrochloric acid, hydrogen is evolved and stannous chloride is formed. The dissolution of tin in this acid is accelerated by the presence of a little platinic chloride, or if the tin is in contact with copper, silver, lead, or platinum. C. Nöllner said that the action of hydrochloric acid ceases when the soln. contains a mol of stannous chloride for every 2 mols of hydrogen chloride. O. P. Watts and N. D. Whipple found that with N-HCl, 0·0016 and 0·0015 grm. per sq. cm. was dissolved from hammered and cast tin, respectively, at 38° in 20 hrs., and if 10 grms. of potassium permanganate were present per 180 c.c. of soln., 0·057 grm. per sq. cm. was dissolved from cast tin. A. J. Hale and H. S. Foster found that $\frac{1}{5}N$-HCl dissolved tin at the rate of 0·42 grm. per sq. dcm. per day during 7 days at 17°–20°, and 0·90 grm. during 28 days. W. G. Whitman and R. P. Russell found that the corrosion of tin by hydrochloric acid is increased in the presence of oxygen. K. K. Järvinen studied the attack of tin by one per cent. hydrochloric acid. According to E. Salkowsky, if hydrogen dioxide be present, free chlorine is developed, and the tin is attacked more vigorously. H. J. Prins found that the presence of easily reducible substances, like benzaldehyde or nitrobenzene, accelerates the attack on tin by acids. C. F. Rammelsberg found that electrolytic tin dissolves about ten times as quickly as tin which has been melted. In the former case, presumably a greater surface area per gram of metal is exposed to the acid. L. P. Cailletet found that under press., acids have very little action on tin. According to W. Vaubel, during the dissolution of polished tin in hydrochloric acid, a black powder is deposited which dissolves only very slowly even in the conc. acid ; it is suggested that this is a peculiar modification of the metal which is produced by the reduction of stannous chloride by nascent hydrogen. He also found that the dissolution of tin in hydrochloric acid produces a gas that has a peculiar metallic odour sometimes resembling the odour of stewed meat. The gas burns with a luminous flame, gives a mirror of metallic tin, and reacts with silver nitrate soln., indicating that it contains a volatile tin compound such as stannous chloride or hydride or a mixture of these. Hot **hydrobromic acid** or **hydriodic acid** also readily dissolves tin. J. L. Gay Lussac showed that with mixtures of hydrochloric and nitric acids, stannous chloride, stannic chloride, or stannic acid may be obtained according to the proportion of nitric acid present. E. Divers and T. Haga also observed the formation of ammonia and hydroxylamine when mixtures of hydrochloric and nitric acids act on tin. A. J. Balard said that dil. **hypochlorous acid** acts on tin only in the presence of other acids ; and that conc.

hypochlorous acid acts only when chloric acid is formed. According to A. D. White, **calcium hypochlorite** in contact with tin furnishes oxygen ; and hypochlorous acid slowly oxidizes tin to stannic oxide with the evolution of chlorine. E. Soubeiran found that soln. of **alkali hypochlorites** act on tin, forming an oxychloride and evolving oxygen—A. J. Balard said the oxygen is mixed with chlorine. S. S. Sadtler found that the presence of hypochlorous acid accelerates the action of sodium hydroxide on tin. W. S. Hendrixson found that **chloric acid dissolves** in tin, forming stannic chloride no hydrogen is evolved, and very little stannic acid is produced.

Tin unites directly with **sulphur** when a mixture of the two elements is heated —*vide* the tin sulphides. The reaction is vigorous and is usually accompanied by incandescence. K. Jellinek and J. Zabowsky[5] made estimates of the affinity of tin for sulphur. P. G. J. Gueterbock and G. N. Nicklin studied the effect of sulphur as an impurity on the physical properties of tin. A. Ditte found that **hydrogen sulphide** does not act on tin at ordinary temp., but at 100°–400°, it forms stannous sulphide. E. Priwoznik showed that **ammonium sulphide** attacks tin, and O. B. Kühn, that when tin is fused with **sodium sulphide**, stannous sulphide is formed. For the action of aq. soln. of these salts, *vide supra*. K. Heumann and P. Köchlin found that **sulphuryl chloride** acts slowly on tin, forming stannic chloride. P. Nicolardot showed that **sulphur monochloride**, S_2Cl_2, attacks tin. A. F. de Fourcroy and L. N. Vauquelin, and C. Geitner found that an aq. soln. of **sulphur dioxide** attacks tin, forming stannous sulphide ; and, according to J. J. Berzelius, and M. J. Fordos and A. Gélis, some stannous thiosulphate, and sulphite are formed. According to K. Heumann and P. Köchlin, **chlorosulphonic acid** acts on tin in the cold, heat is evolved, and the reaction is symbolized : $Sn+4HSO_3Cl=SnCl_4+2SO_2+2H_2SO_4$. Dil. **sulphuric acid** was found by F. C. Calvert and R. Johnson not to react on tin in the cold, but by increasing the conc. of the acid to $H_2SO_4.6H_2O$, action begins. According to A. Ditte, with cold dil. sulphuric acid, hydrogen is given off, and with the hot conc. acid, sulphur dioxide, hydrogen sulphide, and sulphur are formed. M. M. P. Muir and C. E. Robbs showed that with the molar proportions $H_2SO_4 : H_2O$, 7 : 2, at 20°–25°, there is but little action, no hydrogen sulphide is produced, but a little sulphur and a trace of sulphur dioxide are formed, and at 110°–120°, a trace of hydrogen sulphide and much sulphur and sulphur dioxide are produced ; with the 1 : 1 acid at 20°–25°, a trace of hydrogen sulphide and a little sulphur are formed, and at 110°–120°, a little hydrogen and sulphur, some hydrogen sulphide, and much sulphur dioxide are formed ; with the 1 : 3 acid at 20°–25° there is no action, but at 110°–120°, much hydrogen sulphide and a trace of sulphur dioxide are formed ; and with the 1 : 5 acid at 20°–25°, there is no action, and at 110°–120° hydrogen, with a trace of hydrogen sulphide, is given off. O. P. Watts and N. D. Whipple found that with $N\text{-}H_2SO_4$, 0·0006 grm. per sq. cm. of tin was dissolved in 20 hrs. at 38°, and if 10 grms. of potassium dichromate or chlorate per 180 c.c. of acid were present, respectively 0·0003 and 0·1306 grm. per sq. cm. was dissolved. A. J. Hale and H. S. Foster found that with a sq. dcm. of tin and $\frac{1}{5}N\text{-}H_2SO_4$ at 17°–20°, 0·022 grm. per day was lost during 7 days and 0·25 grm. per day during 28 days. H. Bassett found that a mixture of 1 vol. of sulphuric acid, 2 vols. of nitric acid, and 3 vols. of water, dissolves tin in the cold, with the evolution of nearly pure nitrous oxide, producing at the same time a clear soln. of stannic sulphate. If, however, the temp. has been allowed to rise, the soln. becomes opalescent, and on heating in a water-oven for an hour, it becomes nearly solid and opaque. When the soln., containing nitric acid, is poured into boiling water, the whole of the tin is precipitated as metastannic acid. W. G. Whitman and R. P. Russell found that the presence of oxygen favours the attack of tin by sulphuric acid. E. Salkowsky found that the presence of hydrogen dioxide does not affect the rate of dissolution of tin by dil. sulphuric acid. H. Nissenson and E. Crotogino said that if the soln of tin in conc. sulphuric acid is diluted

with water the tin is quantitatively precipitated as stannic acid. E. Divers and T. Shimidzu showed that **pyrosulphuric acid** dissolves tin with the evolution of heat, forming stannous sulphate and sulphur sesquioxide. M. G. Levi and co-workers showed that tin is rapidly attacked by a soln. of **potassium persulphate** or of **ammonium persulphate,** without the evolution of gas, forming stannic oxide, or a metastannic acid. H. Ditz said that when tin is heated with a soln. of ammonium persulphate in dil. sulphuric acid, there is a smell of ozone, and the soln. gradually becomes turbid, and finally stannic hydroxide is precipitated ; the initial darkening of the soln. is supposed to be due to the formation of stannous oxide. Tin reacts vigorously with **selenium** or **tellurium** when a mixture of the two is heated—*vide* selenides and tellurides. E. B. Hutchins found that tin is attacked by hot **telluric acid.**

Tin does not form a compound by direct union with **nitrogen.** F. Fischer and G. Iliovici [6] passed arc and spark discharges beneath liquid nitrogen, and obtained a mixture of metal, tin nitride, and some oxide. T. Curtius and co-workers found that tin is attacked by a 17 per cent. soln. of **hydrazoic acid,** a gas is developed containing a large proportion of ammonia, and a non-explosive product is formed. C. Matignon and G. Desplantes showed that tin is not changed by aq. **ammonia** even in the presence of oxygen. A. J. Hale and H. S. Foster found that $\frac{1}{5}N$-NH_4OH did not dissolve anything from tin during 28 days at 17°–20°. G. G. Henderson and J. C. Galletly found that ammonia at 170° is decomposed by tin, but no nitride is formed. F. W. Bergstrom represented the reaction with a soln. of **alkali amide** in liquid ammonia : $10Sn + 6KNH_2 = 2SnNK(NH_3)_2 + K_4Sn_8$. E. Divers and T. Haga reported that **hydroxylamine hydrochloride** is not perceptibly changed by tin and hot hydrochloric acid. According to E. Ludwig and T. Hein, and E. Divers and T. Haga, when **nitric oxide**—in the absence of air—is passed into a mixture of tin and hydrochloric acid, hydroxylamine, but no ammonia, is formed. E. Müller and H. Barck found that nitric oxide does not act on tin at temp. below 400° ; at 450°, a tin nitride is formed ; less nitride is produced at 500°, and none at 600°. R. Weber said that tin is inert towards nitrogen pentoxide. R. Boyle remarked on the action of aqua fortis in " eating up or destroying " more tin than it dissolves ; and J. J. Berzelius showed that hot **nitric acid** oxidizes tin completely to hydrated stannic oxide. S. L. Mitchill said that conc. nitric acid does not act on tin, but if water be added the metal dissolves. R. Weber said that dil. or conc. nitric acid dissolves the metal without the evolution of gas provided the temp. is kept low ; and G. Hay, that dil. nitric acid dissolves tin, forming a straw-yellow liquid which is decomposed on boiling. E. J. Maumené showed that the products of the action of nitric acid on tin vary with the temp. and conc. of the acid ; but the dil. acid—$HNO_3.4H_2O$—can produce stannous oxide which for the most part remains undissolved. A. J. Hale and H. S. Foster found that with $\frac{1}{5}N$-HNO_3 the loss of metal per sq. dcm. at 17°–20° was 4·0 grms. per day in 7 days and 7·20 grms. per day in 28 days. It is generally supposed that the soln. of tin in dil. nitric acid contains stannous nitrate ; R. Engel, indeed, said that with nitric acid of sp. gr. 1·42 diluted with two vols. of water, at 0°, stannous nitrate gel is formed, but if diluted with one vol. of water, stannic nitrate is produced. J. J. Acworth and H. E. Armstrong obtained at 11°–14° the following results :

TABLE IV.—ACTION OF NITRIC ACID ON TIN.

Conc. of acid.	Gram tin.	C.c. of gas.	Percentage composition of gas.		
			NO.	N₂O.	N₂.
1 : 0	0·4135	21·54	1·08	85·14	13·78
1 : 1	0·4140	31·02	16·38	73·82	9·80
1 : 2	0·4145	33·09	14·47	75·55	9·98
1 : 8	0·4150	4·66	3·27	85·02	11·80

According to C. Montemartini, nitric acid, up to a conc. of 12 per cent., always attacks tin with formation of stannous salt, which partially decomposes, forming a turbid soln.; gas is always evolved, although slowly. Nitric acid, of a conc. from 12 to 45 per cent., completely dissolves the metal to a yellow soln., with abundant evolution of gas; the soln., when left, slowly becomes turbid, but the precipitation may be retarded by adding hydrochloric acid. The tin is present in these soln., as stannous nitrate, and the turbidity is due partly to the oxidation of this salt and partly to its conversion into insoluble stannous compounds, which, in turn, yield hydrated stannic oxide. Nitric acid of more than 45 per cent. conc. does not dissolve tin, but converts it into a white substance. If 70 per cent. acid is used, this white oxidation product is soluble in water, but the soln., after a few seconds, becomes turbid, and hydrated stannic oxide is deposited; the addition of hydrochloric acid to the clear soln. greatly retards the precipitation. The soluble, white substance is stannic nitrate, $Sn(NO_3)_4$; it is stable in presence of conc. nitric acid at 90°, but is immediately decomposed at 100°. The soln. of a gram of tin in excess of 27·5 per cent. acid yields 0·0180 grm. of ammonia, 0·1060 grm. of nitrous oxide, and 0·0051 grm. of nitrogen. The maximum quantity of ammonia is obtained when one per cent. nitric acid is used, but the rate of diminution in the amount of this gas produced, as stronger acid is used, is small; even 70 per cent. acid causes the formation of much ammonia. The hypothesis that the nitric acid is reduced by nascent hydrogen is insufficient for the explanation of the phenomena observed during the action of nitric acid on tin. E. Divers and co-workers said that the action of nitric acid on tin resembles in some respects its action on zinc (q.v.). C. H. H. Walker concluded from his observations that metallic tin dissolves in nitric acid, forming both a stannous and a stannic salt, according to the conditions of temp. and the conc. of the acid. The proportion of stannous salt formed is but little affected by the mass of tin present. In the case of very dil. acids, increase of temp. causes a slight decrease in the proportion of stannous salt, but in the case of more conc. acid, the effect is more marked, so that an alteration of 10° reduces the amount of stannous salt to nil. An increase in the conc. of the acid, other conditions remaining the same, decreases the amount of stannous salt. The white or yellowish-white substance deposited from fairly conc. soln. is a hydrated stannic nitrate of rather indefinite composition. F. H. van Leent said that in the presence of iron, chromium, or aluminium, tin is wholly converted by conc. nitric acid into insoluble stannic acid, while the other products pass into soln. A. Quartaroli also studied this reaction, and found that in the presence of 4 per cent. of urea, tin is dissolved as stannous nitrate without the appearance of insoluble stannic nitrate. W. G. Whitman and R. P. Russell found that the presence of oxygen favoured the attack of tin by nitric acid. For H. Bassett's work on the action of a mixture of sulphuric and nitric acids on tin, vide supra. R. Weber found that moist **potassium nitrate** does not act on tin, but with **copper nitrate,** an explosive basic nitrate is formed—vide basic stannous nitrates; and L. Loviton showed that fused **ammonium nitrate** does not affect tin at 150°.

From the observations of B. Pelletier,[7] O. Emmerling, C. Künzel, S. Natanson and G. Vortmann, and A. Schrötter, molten tin unites with **phosphorus,** forming a phosphide. A. C. Vivian found that when mixtures of tin and yellow phosphorus are heated in sealed glass tubes, alloying commences as soon as the tin is molten, for an appreciable amount of the alloy is formed at 400°; with red phosphorus, no evidence of alloying occurs below the temp. at which the red changes to yellow phosphorus. At 400°, only very little alloying had occurred. Phosphorus also appears to be quite insoluble in solid tin. R. Lüpke melted tin covered with ammonium carbonate in a crucible and added the calculated quantity of red phosphorus; A. Schrötter, and P. Vigier passed phosphorus vap. mixed with carbon dioxide into molten tin; G. Landgrebe melted equal parts of tin and fused microcosmic salt; P. Berthier heated in a carbon crucible a mixture of tin filings or stannic oxide, carbon, quartz, boric acid, and bone-ash, and P. Mellmann, and J. L. Sey-

both used an analogous process. S. Natanson and G. Vortmann heated a mixture of metaphosphoric acid, carbon, and tin ; and A. Granger, a mixture of tin and phosphorus chloride at 500°. H. Rose treated stannic phosphine chloride with water, and found that tin phosphide was precipitated ; when dried out of contact with air, the composition approximated SnP_4. The phosphor-tin used in making phosphor bronze was discussed by F. von Friese, R. F. Nursey, and W. G. Otto—vide the tin phosphides. J. Heimann found tin to be soluble in a soln. of **metaphosphoric acid.** E. Baudrimont [8] found that **phosphorus pentachloride** reacts on finely granulated tin at 170°, forming a complex $SnCl_4.PCl_5$; but, according to H. Goldschmidt, the reaction is $Sn+2PCl_5=SnCl_4+2PCl_3$. B. Reinitzer and H. Goldschmidt found that **phosphorus oxychloride** reacts with tin at 100° without forming phosphoric oxide.

According to T. Bergman,[9] molten tin can take up half its own weight of arsenic, and the product is lustrous and white. A. F. Gehlen, and A. Vogel found that when pulverized **arsenic** is stirred about in melted tin, the union of the elements is attended by the evolution of heat and light. The former also obtained an alloy by heating tin with arsenic trioxide. C. Bülles obtained the alloy in a similar way. A. Descamps heated the two elements under a layer of boric acid fused at the lowest possible temp. and obtained a brittle mass which he regarded as *tin hemitriarsenide*, Sn_2As_3. W. Spring exposed a mixture of the two elements to a great press. and obtained what he regarded as *tin tetratritarsenide*, Sn_3As_4 ; P. Jolibois and E. L. Dupay obtained *tin tritetritarsenide*, Sn_4As_3, by the action

FIG. 18.—Fusion Curves of Binary [Mixtures : As-Sn.

of a soln. of ferrous chloride, on an alloy with 7 per cent. of arsenic used as the anode of a cell ; and W. P. Headden obtained six-sided plates of what he regarded as *tin hexitarsenide*, Sn_6As, from the hearth of an old dismantled tin furnace of the Trethellan Tin Works, Truro, Cornwall. There is no other evidence of the individuality of these products. J. E. Stead isolated **tin ditritarsenide,** Sn_3As_2, from alloys of the two elements ; N. A. Puschin obtained evidence of the same compound from his measurements of the e.m.f. of the cells Sn | N-H_2SO_4 | $SnAs_n$; and Sn | N-KOH | $SnAs_n$. The crystals of the tritadiarsenide obtained by J. E. Stead in an alloy of tin with 5 per cent. arsenic are shown in Fig. 19. According to N. Parravano and P. de Cesaris, the fusion curves of mixtures of the two elements, show the existence of both tin tritadiarsenide and **tin monoarsenide,** SnAs. P. Jolibois and E. L. Dupay prepared the latter compound. Q. A. Mansuri's equilibrium curve is shown in Fig. 18, where the two
FIG. 19.—Crystals of Tin Tritadiarsenide, Sn_3As_2. ×2.

eutectics are denoted by E_1 and E_2, and the solid soln. by the Greek letters. N. A. Puschin commented on the great hardness imparted to tin when alloyed with arsenic, and he noted the great tendency of the alloys to crystallize. According to E. Soubeiran, the alloy is white, sonorous, and brittle if the arsenic be not in too great an excess. The texture is lamellar. W. Campbell examined the micro-structure ; and M. Padoa, the electrical conductivity. When fused in an open vessel, arsenic is evolved ; and with hydrochloric acid, arsenic hydride is evolved ; an alloy with an excess of arsenic is not attacked by this acid. P. G. J. Gueter-bock and G. N. Nicklin studied the effect of arsenic as an impurity on the physical properties of tin.

Molten tin dissolves **antimony,** and the two elements unite without the evolution of heat or light. The alloy can also be made by fusing antimony sulphide with an excess of tin. C. W. G. Kastner [10] noted that an alloy with 12·5 per cent. of anti-mony has a fine musical tone ; and L. J. Chaudet noted that a 10 : 1 alloy is quite ductile, while the 3 : 1 alloy is less ductile than tin, and the 1 : 1 alloy is extremely brittle and readily pulverized. The brittle alloys are more ductile if a small amount of lead be present. He added that alloys with more than 90 per cent. of tin give up the whole of the tin to boiling hydrochloric, leaving the antimony as a black powder—some stibine is evolved. The various physical properties were studied by A. W. Smith, and P. G. J. Gueterbock and G. N. Nicklin. R. Kremann and P. G. von Rehenburg found that on electrolysis, the tin accumulates at the anode, the antimony at the cathode. A. Wagner said that the alloy with 10 per cent. of antimony, in the presence of air free from carbon dioxide, is attacked quickly by
FIG. 20.—Fusion Curves of Binary Mixtures : Sn–Sb.

soln. of sodium chloride ; and slightly by soln. of sodium carbonate or nitrate, ammonium chloride, potassium sulphate or magnesium chloride ; and not at all by water or lime-water. If the carbon dioxide of the air has also access, soln. of ammonium chloride and potassium sulphate have no action, and soln. of alkali chlorides, magnesium chloride, and sodium nitrate have very little action. L. J. Chaudet examined the action of hydrochloric acid. Accord-ing to A. Czerwek, the tin-antimony alloys are dissolved by a mixture of nitric and tartaric acids. J. R. Johnson, C. Karmarsch, H. Gautier, L. J. Thénard, A. M. Fairlie, R. H. Thurston, F. G. Thompson and F. Orme, and W. Campbell made observations on the properties of these alloys with or without the addition of other metals. The last-named examined the ternary alloys with copper, silver, zinc, cadmium, aluminium, lead, arsenic, and bismuth. The tin-antimony alloys form the base of the so-called *britannia metal*, which is mainly tin hardened with antimony, and contains 6·0 to 9·2 per cent. of antimony; *algiers metal* has 10 to 25 per cent. of antimony ; 33 per cent. marks the extreme limit of these alloys, when the latter is very hard. Numerous modifications of the alloy employed in commerce are associated with zinc, bismuth, lead, and copper. H. Gautier, and A. Matthiessen showed that the sp. gr. of the tin-antimony alloys is rather less than that calculated from the sp. gr. of the components ; consequently, an expansion takes place when the metals are alloyed. M. Chikashige studied the colour of the alloys; E. von Maey, the sp. vol.; E. Elsässer, the electrical conductivity of these alloys ; and N. S. Konstantinoff and W. A. Smirnoff, working at 25°, obtained the results plotted in Fig. 20. C. T. Heycock and F. H. Neville noted that the m.p. of a dil. soln. of antimony in tin is higher than that of tin alone ; A. van Bijlert tried to find if solid soln. of the two elements are formed. F. W. Küster, and F. E. Gallagher observed no evidence of chemical combination although they considered that crystals of four different solid soln. were produced. G. Charpy said that although solid soln. are produced, alloys with 10–40 per cent.

of antimony contain well-formed cubic crystals of **tin monantimonide,** SnSb ; H. Behrens made a similar observation ; and J. E. Stead added that alloys with 7·5 per cent. of antimony contain some of these crystals. They are particularly well-formed in alloys with 25 per cent. of antimony ; and alloys with over 40 per cent. antimony contain tabular crystals. The crystals of tin antimonide obtained by J. E. Stead in an alloy of tin with 20 per cent. of antimony are illustrated in Fig. 21. G. Tammann and K. Dahl measured the plastic deformation. H. Gautier, T. Thompson, C. R. A. Wright, W. Reinders, R. S. Williams, N. S. Konstantinoff and W. A. Smirnoff studied the f.p. of the thermal diagram. R. S. Williams' curves are shown in Fig. 20. There are breaks at 243° and 420°, but none corresponding with the break at 310°-319° observed by F. E. Gallagher, and W. Reinders. By keeping the

FIG. 21.—Crystals of Tin Antimonide, SnSb. ×50.

alloys at a high temp. for some hours, three series of mixed crystals were formed containing 0-8, 49·8-52·8, and 90-100 at. per cent. of antimony. The end-
FIG. 22.—Electrical Conductivities of the Sn-Sb Alloys.
FIG. 23.—Magnetic Susceptibilities of the Sn-Sb Alloys.

member of the middle series may be regarded as tin monantimonide. G. Charpy, W. Campbell, and H. Behrens and H. Baucke examined the microstructure of these alloys. N. S. Konstaninoff and W. A. Smirnoff obtained evidence of the formation of **tin ditritaantimonide,** Sn_3Sb_2, on the f.p. curve ; and N. A. Puschin measured the e.m.f. of the cells $Sn \mid SnCl_2 \mid SnSb_n$; $Sn \mid N\text{-}H_2SO_4 \mid SnSb_n$; $Sn \mid N\text{-}KOH \mid SnSb_n$, and obtained breaks corresponding with tin monantimonide and tin tritadiantimonide, Sn_4Sb_2. G. Wertheim studied the elastic properties ; and A. W. Smith, the thermal conductivity. The magnetic susceptibilities of these alloys were measured by H. Endo, and P. Leroux, and the results are plotted in Fig. 23. W. Rollmann, A. Naccari and M. Bellate, and A. Battelli investigated the thermoelectric properties ; and C. C. Hutchins' measurements are graphed in Fig. 24.

FIG. 24.—Thermoelectric Powers of the Sn-Sb Alloys.

A. P. Laurie, and H. le Chatelier measured the e.m.f. of cells with an electrode of these alloys. W. Campbell, and J. E. Stead studied the ternary system :

Sn–Sb–As. A. Mazzucchelli and A. Vercillo found that antimony trichloride and tin form **tin diantimonide,** $SnSb_2$.

According to F. Rudberg,[11] when a molten alloy of tin with 54·6 per cent. of **bismuth** is cooled, there is a fairly sharp f.p. at 143°; but alloys with other proportions of these elements have two f.p. The higher *point of separation* is accompanied by the separation of the excess of one or other metal, or of a definite alloy with an excess of one of the metals, until the composition of the remaining fluid has 54·6 per cent. of bismuth, when all solidifies at 143°. F. Rudberg found the point of separation to be variable, for with the proportions Sn : Bi=8 : 1 it was 190°; 2 : 1, 150°; 4 : 3, 170°; and 1 : 1, 190°. He regarded the lowest melting alloy as a definite compound, Sn_3Bi. P. G. J. Gueterbock and G. N. Nicklin studied the effect of bismuth as an impurity on the physical properties of tin. Observations on the m.p. of specific mixtures were made by L. J. Chaudet, C. M. Marx, W. Lewis, H. V. Regnault, J. W. Döbereiner, H. von Jüptner, A. Matthiessen, A. Riche, J. Würschmidt, D. H. Andrews and J. Johnston, K. Honda and T. Ishigaki, etc. F. Guthrie gave 133° for the eutectic temp., for an alloy with 46·1 per cent. of bismuth. E. S. Shepherd said that no *tin bismuthide* is formed. Thermal analyses have been made by A. Bucher, A. Stoffel, A. W. Kapp, and W. von Lepkowsky, and the results are indicated in Fig. 25. The phenomena were also studied by C. T. Heycock and F. H. Neville, C. R. A. Wright, H. Gautier, F. Guthrie, T. Thomson, C. L. Weber, A. W. Smith, and G. Charpy. D. H. Andrews and J. Johnston studied the solubility of bismuth in tin. H. Behrens and K. Bux investigated the microstructure; and C. H. Green, and A. M. Portevin, the structure of the eutectic. The sp. gr. of the alloys were determined by T. Thomson, H. V. Regnault, A. Matthiessen, and A. Riche, and the sp. vol. by E. von Maey, and K. Gilbert; K. Bornemann and P. Siebe, and K. Gilbert measured the sp. vols. of the alloys up to 900° and found them to be proportional to the temp. C. di Capua measured the hardness; M. Plüss, the viscosity and sp. gr. of the liquid; G. Wertheim, the elastic constants; A. Matthiessen, the coeff. of thermal expansion; and G. Vicentini and D. Omodei, D. Mazzoto, and C. C. Person, the latent heat of fusion; H. Kopp, and A. Schulze, the sp. ht.; A. Levi, the mol. heat; and L. H. Adams and co-workers, the coeff.

FIG. 25.—Fusion Curves of Binary Mixtures Sn–Bi.

of compressibility of the alloys. C. R. Darling and R. H. Rinaldi studied the thermoelectric properties of the alloy against copper. F. A. Schultze's results for the thermal and electrical conductivities are plotted in Fig. 26. The electrical conductivity and resistance of the alloys were measured by A. Righi, G. Wiedemann, C. L. Weber, A. Sundell, A. Bucher, E. van Aubel, A. Matthiessen and C. Vogt, F. A. Schultze, and G. Vicentini and C. Cattaneo. R. Kremann and P. G. von Rehenburg found that on electrolysis, the tin accumulates at the cathode, the bismuth at the anode. H. Pélabon measured the thermoelectric power. G. Faè studied the effect of a magnetic field on

FIG. 26.—Thermal and Electrical Conductivities of the Tin-Bismuth Alloys.

the electrical resistance. A. P. Laurie, H. le Chatelier, E. S. Shepherd, and A. Sundell studied the e.m.f. of cells with these alloys as electrodes; the thermoelectric power was measured by A. Matthiessen, G. Spadavecchia, A. Sundell, G. Vicentini and D. Omodei, H. Pélabon, C. C. Hutchins, A. Battelli, E. Becquerel, W. Rollmann, and A. E. Caswell and C. A. McKay. The results are plotted in Fig. 27. The curve for the Thomson effect by S. C. Laws, and A. E. Caswell and C. A. McKay is shown in Fig. 27. A. von Ettinghausen and W. Nernst, and

E. van Aubel studied the thermoelectric phenomena. A. Righi, S. C. Laws, and E. van Aubel studied the magnetic susceptibility of the alloys, and the results of T. Gnesotto and M. Binghinotto are shown in Fig. 28. C. R. A. Wright investigated the ternary system Sn–Bi–Al; C. di Capua, the hardness of the Zn–Bi–Cd alloys; and W. Campbell, the system Sn–Bi–Sb. F. E. Brown and J. E. Snyder [12] observed that **vanadium oxytrichloride** has no action on tin.

H. Moissan [13] said that tin does not unite directly with **carbon** to form a carbide (*q.v.*). O. Ruff and B. Bergdahl said that molten tin dissolves only a trace of carbon. E. Gudeman found that water sat. with **carbon dioxide** attacks tin. F. H. Rhodes
FIG. 27.—Thermoelectric Properties of the Tin-Bismuth Alloys.
FIG. 28.—Magnetic Susceptibilities of the Tin-Bismuth Alloys.

and J. T. Carty found tin is resistant to the moist vapour of carbon tetrachloride; there is a slight pitting of the surface. W. R. Hodgkinson showed that tin is unaffected by **acetylene** at temp. up to its m.p. F. Malméjac said that tin is appreciably attacked by **alcohol** in the course of six months; but G. Heinzelmann denied this. W. Ipatieff found that if alcohol vapour be passed through a glass tube containing tin at 660° no decomposition occurs, but finely divided tin obtained by the reduction of the oxide forms acetaldehyde and ethylene. J. Trummer discussed the action of tin on **wine ;** and F. Schönfeld, J. Dehnicke, L. Nathan and A. Schmidt, K. Dinklage, and C. Sellenscheidt, on **beer.** H. Fleck, and F. P. Hall observed that tin is but slightly attacked by **organic acids,** but if air be present, the metal may be dissolved ; thus, **acetic, tartaric, and citric acids** act on the metal in the presence of air ; and W. G. Whitman and R. P. Russell found that the presence of oxygen favoured the attack by acetic acid. E. Salkowsky said that the presence of hydrogen dioxide does not affect the dissolution of tin by glacial acetic acid. A. Hébert found that **stearic acid** is decomposed by distillation over finely divided tin; and J. H. Matthews showed that **trichloroacetic acid,** in nitrobenzene soln., is blackened by tin, but no aniline is formed. F. H. Jeffery studied the effect of tin anodes on **potassium oxalate** soln. F. A. Norton found that **organic substances** in the presence of sodium sulphite form stannic sulphide. C. F. Böhringer studied the electrolytic reduction of **nitro- and azo-compounds** by a cathode of spongy tin. O. W. Brown and C. O. Henke found tin an excellent catalytic agent in reducing nitrobenzene by hydrogen ; and A. Korczynsky. in the bromination of benzene. For the action of tin on **food-stuffs,** *vide supra,* the occurrence of tin. E. Gudeman emphasized the solubility of tin in the liquids used with canned food products, and in the peculiar liquids produced in the decomposition of foods. D. Klein and A. Berg said that hot soln. of **sugar** do not attack tin ; but K. K. Järvinen found that the metal is attacked by 30 per cent. soln. of sugar. J. Merrick found that tin is but slightly affected by **turpentine ;** and F. Pfaff observed a similar result with **fatty oils.** I. J. Redwood said that at ordinary temp. tin is not attacked by **rape oil,** and **whale oil ;** and the percentage loss with **olive oil** was 0·01637 ; **tallow oil,** 0·03400 ; **lard oil,** 0·01976 ; **cotton-seed oil,** 0·46075 ; **sperm oil,** 0·22847 ; with **seal oil,** 0·08503 ; and with a mineral lubricant, 0·02587. A. Gawalowsky observed no action between tin and **petroleum or mineral oils ;** and U. Ehrhardt and G. Pfleiderer found 0·22 mgrm. of tin per sq. cm. was dissolved in 4 weeks by crude **tar oils** containing phenol.

J. J. Berzelius, and C. Winkler found that molten tin dissolves some **silicon**—but E.. Vigouroux said that no tin silicide is formed (*q.v.*).   H. Moissan said that tin alloys with **titanium.**   G. Tammann and P. Schafmeister [14] measured the partition of tin between lead and zinc, lead and aluminium, and zinc and bismuth.

The physiological action of tin.—According to J. D. Mann,[15] no fatal case of poisoning by tin salts had been recorded up to 1908 ; and cases of poisoning by this agent are extremely rare and have resulted only from accident—generally the use of tinned meat and fruit.   Cases have been recorded by A. P. Luff and G. H. Metcalfe, T. L. Phipson, B. Dyer, R. Kayser, T. Günther, E. Ungar and G. Bodländer, A. Eckardt, F. P. Wightwick, and W. A. Campbell.   W. Vaubel found that stannous salts are only slightly poisonous, but they are readily oxidized to the more poisonous stannic salts.   G. Pouchet and co-workers emphasized the harmful nature of the one-time practice in Belgium and France of putting stannous chloride—up to 2·5 per cent.—into ginger-bread in order to obtain with inferior materials an appearance like that due to fine flour.   Experiments by O. Hehner, and T. P. White, on animals show that tin compounds are toxic ; and F. Jolyet and A. Cahours found the tin alkyl compounds to be very poisonous.   The rarity of tin poisoning contrasted with the extended use of that metal for cooking vessels show that the risks are very small ; and, according to K. B. Lehmann, no case is known of chronic tin-poisoning from the consumption of canned foods.   If the tin is alloyed with lead, R. Weber, and G. Ambühl showed that lead poisoning may occur.   There are no special pharmaceutical preparations of tin or of its compounds, although powdered tin has been recommended for tape-worms.   F. Marcet also found tin to be poisonous to plants.   H. Micheels and P. de Heen found that colloidal tin exercises a stimulating action on germinating wheat ; and G. Gimel found that a trace of stannous chloride (1 : 10000) stimulates the alcoholic fermentation of yeast.

Some reactions of analytical interest.—No precipitation occurs when stannous salts are treated with **hydrochloric acid,** but conc. soln. of stannous salts become turbid in aq. soln. owing to oxidation : $3SnCl_2+O+H_2O=2Sn(OH)Cl+SnCl_4$; the formation of the basic salt is prevented by hydrochloric acid, and oxidation is prevented by keeping the acidic soln. in contact with granulated tin.   The soln. of stannic chloride are hydrolyzed by water : $SnCl_4+4H_2O \rightleftharpoons 4HCl+Sn(OH)_4$.   Moderately conc. soln. of stannic chloride give no precipitate with hydrochloric acid or **sulphuric acid** even on long standing, but with soln. of β-stannyl chloride, sulphuric acid precipitates white stannyl sulphate.   A very dil. sulphuric acid soln. of ordinary stannic chloride, sometimes gives a precipitate of basic sulphate ; and a dil. hydrochloric acid soln. may become turbid on boiling, owing to hydrolysis.   When **hydrogen sulphide** is passed into soln. of a stannous salt, not acidified too strongly, brown stannous sulphide, SnS, is precipitated (*q.v.*).   This precipitate is soluble in conc. hydrochloric acid, so that no precipitation occurs if a large proportion of acid be present.   The precipitation is complete in soln. weakly acidified.   For L. Dede and P. Bonin's [16] observations on the effect of the conc. of the acid and the presence of chloride, *vide* the analytical reactions of lead, which are said to be similar in the case of tin.   According to F. Jackson, a visible coloration is produced if the soln. has 1 part of tin in 64,000 ; C. H. Pfaff said 1 in 120,000.   According to F. W. Clarke, oxalic acid hinders the precipitation.   H. N. Warren also found ferrocyanides hinder the precipitation.   Unlike arsenic and antimony sulphides, stannous sulphide is insoluble in aq. ammonia, ammonium carbonate, or colourless ammonium sulphide ; stannous sulphide dissolves in yellow ammonium sulphide, forming ammonium sulphostannate, $(NH_4)_2SnS_3$, and if the soln. be acidified yellow stannic sulphide is precipitated : $(NH_4)_2SnS_3+2HCl=2NH_4Cl+H_2S+SnS_2$. Stannous sulphide is soluble in soln. of potassium or sodium hydroxide, so that the sulphide is not precipitated by hydrogen sulphide from strongly alkaline soln. If heated in a stream of chlorine, or of bromine vap. and carbon dioxide ; or if heated with a mixture of ammonium chloride and nitrate, stannous sulphide is completely

decomposed and volatilized. Hydrogen sulphide precipitates stannic sulphide from both α- and β-stannic salt soln. if they are not acidified too strongly. If strongly acidified, no precipitation occurs because the sulphide is soluble in the acid. With β-salts, the precipitate is formed slowly and in the hydrosol form unless flocculating salts are present. According to F. Jackson, a coloration can be detected with one part of tin in 32,000 parts of liquid. The precipitation is hindered by oxalic acid (F. W. Clarke)—*vide infra*, stannic sulphide. F. Fischer and K. Thiele found that hydrofluoric acid hinders the precipitation with stannic but not stannous or antimony salts; and G. Vortmann and A. Metzl, the presence of phosphoric acid hinders the precipitation of stannic sulphide, but not antimony sulphide. Yellow stannic sulphide is soluble in alkali sulphide soln. from which acids re-precipitate the yellow sulphide. The sulphide is almost insoluble in aq. ammonia, ammonium carbonate, or potassium hydrosulphite; but it readily dissolves in soln. of potassium or sodium hydroxide, sodium dioxide, alkali polysulphide, conc. boiling hydrochloric acid, aqua regia, or a soln. of oxalic acid. It dissolves incompletely in a soln. of ammonium monosulphide. It is converted into stannic acid by nitric acid, and into stannic oxide by roasting in air. A soln. of **ammonium sulphide** precipitates hydrated stannous sulphide from stannous salt soln., and hydrated stannic sulphide from stannic salt soln. The precipitate is soluble in excess as indicated above. The corresponding sulphide is precipitated from stannous or stannic salt soln. by **ammonium thioacetate,** and if the soln. is warm the precipitation is complete. G. Vortmann found that **sodium thiosulphate** gives a white precipitate with stannous and stannic salt soln., the white precipitate in both cases being a mixture of stannic hydroxide and sulphide. According to E. Donath, stannous salts reduce **sulphur dioxide,** forming stannic chloride: $3SnCl_2+6HCl+SO_2=H_2S+2H_2O+3SnCl_4$. The hydrogen sulphide acts on both the stannic and stannous salt. O. Brunck said that **sodium hydrosulphite** precipitates stannous hydrosulphite from stannous salt soln., and A. Röhrig said that the precipitate is a basic sulphite. An excess of **alkali sulphate** may precipitate β-stannic acid from soln. of salts of β-stannic acid, but not of α-stannic acid.

Stannous salt soln. give a voluminous, white, gelatinous precipitate of stannous hydroxide when treated with **alkali hydroxide ;** the precipitate is soluble in excess, forming alkali stannite, say, K_2SnO_2 ; it is also soluble in hydrochloric acid, forming stannous chloride. The precipitate often blackens, particularly if the soln. be heated or a conc. soln. of alkali-lye be used. The blackening is due either to the formation of stannous oxide : $Sn(OK)_2+H_2O=2KOH+SnO$; or the separation of finely divided tin : $2Sn(OK)_2+H_2O=2KOH+Sn+SnO(OK)_2$. The precipitation is hindered by tartaric acid. A similar precipitate is obtained with aq. **ammonia** or **alkali carbonate,** but the precipitate is very sparingly soluble in an excess. With a soln. of α-stannic salts, the precipitate produced with alkali hydroxide is likewise soluble in excess ; the precipitated hydroxide also dissolves in aq. ammonia in the absence of ammonium salts. With soln. of β-stannic salts, alkali hydroxides give a precipitate of β-stannic acid not soluble in an excess unless the precipitant is dil., for the resulting alkali β-stannate is soluble in water and dil. alkali hydroxide. The precipitation of β-stannic salts with aq. ammonia gives β-stannic acid and, unlike the result with α-stannic salts, the precipitation occurs in the presence of tartaric acid. The precipitate of α-stannic acid is obtained by adding **alkali carbonate** to a soln. of a stannic salt. α-stannic acid is soluble in excess; this is not the case with the precipitate obtained from β-stannic salt soln. According to F. Jackson, the precipitation by ammonia with stannous salts is sensitive to 1 : 8000, and with stannic salts to 1 : 4000 ; and with sodium hydroxide in both cases to 1 : 2000. H. Demarçay, and E. Frémy found that barium, strontium, calcium, and magnesium carbonates precipitate the hydroxide from stannic salts even in the cold.

A white precipitate of mercurous chloride is produced by **mercuric chloride** with soln. of stannous salts, and if stannous salt be in excess, the precipitate will become

grey owing to the separation of mercury. Stannic salts give no precipitate with mercuric chloride. A trace of a stannous salt added to a soln. of **auric chloride** gives a separation which is brown by transmitted light and bluish-green by reflected light—*vide* gold, and purple of Cassius (3. 23, 6 and 11); no precipitate occurs with stannic salts alone. According to L. Vanino and F. Treubert, a soln. of alkali stannite when treated with **bismuth nitrate** gives a white precipitate: $Bi_2O_3 + K_2SnO_2 = K_2SnO_3 + 2BiO$, which rapidly blackens: $BiO + K_2SnO_2 = K_2SnO_3 + Bi$. Stannous salt soln. give a white precipitate with **potassium ferrocyanide** soluble in hydrochloric acid; the white precipitate with **potassium ferricyanide** behaves similarly. With stannic salt soln., potassium ferrocyanide slowly forms a white turbidity, and finally a yellow, gelatinous precipitate insoluble in hydrochloric acid; potassium ferricyanide gives no precipitate with stannic salts. A mixture of ferric chloride and potassium ferricyanide was found by J. Löwenthal to give a precipitate of Berlin blue in contact with stannous chloride; the reaction is very sensitive. L. Blum added **ferric chloride** to stannous chloride, and tested the resulting ferrous chloride by the brown colour produced with sulphuric acid and potassium nitrate. According to J. Fages, **sodium nitroprusside** in alkaline soln. gives with stannous salts a greyish-red colour which turns blue when hydrochloric acid is added. J. P. Longstaff found that **ammonium molybdate** gives a blue coloration with stannous salts, enabling one part of the latter to be detected in 1,500,000 parts of soln. G. Denigès said other reducing agents must be absent. Stannous chloride gives a yellowish-white precipitate with **potassium iodide,** and with an excess of the reagent, orange, needle-like crystals of a double salt are formed, and with conc. soln. stannic chloride gives a yellow precipitate. Stannous salts give a white precipitate with **oxalic acid,** but not stannic salts. Stannous salts give a yellow precipitate with **tannin.** J. Löwenthal found that stannous chloride gives a yellow coloration with β-stannic acid. White precipitates are formed when **sodium phosphate** is added to a soln. of stannous or a stannic salt. According to C. H. Pfaff, **succinic acid** and the **alkali benzoates** give white precipitates with stannous salts visible when the dilution is 1 : 10000; and J. J. Berzelius found stannic salts are precipitated completely by **ammonium succinate.** J. von Liebig found that when a stannic chloride soln. is boiled with **sodium acetate** or **potassium formate,** a precipitate is formed which re-dissolves on cooling. C. Reichard observed a darkening occurs when uric acid is moistened with a drop of soln. of stannic chloride, not stannous chloride, and warmed with conc. soda-lye.

The metallic precipitation of tin.—According to N. W. Fischer,[17] when **zinc** or **cadmium** is immersed in an aq. soln. of a stannous or stannic salt, tin is deposited in an arborescent or dendritic form called *tin-tree*, or *arbor jovis*. Stannous acetate, however, is not reduced under these conditions. Tin is reduced by **iron** from the chloride or acetate provided the iron is made to dip into water in which is likewise immersed a bladder containing the tin-soln. so that the latter may mix very slowly with the water by endosmosis. Iron does not precipitate tin from a boiling soln. of stannous chloride. B. Schulze said that iron precipitates tin only from neutral soln., and when ferrous salts alone are present. J. Thiele said that electrolytic iron readily precipitates tin from its salt soln., but not if the iron has been heated to redness. N. Bouman found *ferrum reductum* will precipitate tin from soln. of stannous chloride with $2N$-HCl; but I. M. Kolthoff found that in hydrochloric acid soln., tin is not precipitated by iron. N. Bouman measured the potentials of the tin and iron in the soln. of stannous chloride. At the beginning, the potential of the iron was −505, and that of tin, −533·5; after an hour, the potentials of both were −603, and nearly all the tin had been precipitated. H. Reinsch said that **copper** precipitates tin from strongly acid soln. of the chloride and particularly if the soln. be boiling. Tin is readily precipitated from its salt soln. by **magnesium** or **aluminium.** With magnesium powder, said H. Mouraour, much hydrogen is evolved. When **lead** is first immersed in a soln. of a salt tin, some tin is precipitated in small needles, but the action ceases as soon as the lead becomes covered with a

coating of metallic tin. On the other hand, A. Pleischl said that tin is quantitatively precipitated by lead from soln. of the nitrate or chloride. According to M. Lazowsky, soln. of tin salts are reduced by **charcoal,** and the metal is deposited on the carbon.

The uses of tin.—On account of its silvery-white colour, its resistance to atmospheric influences and chemical agents, its low fusing temp., and its malleability, tin is used excessively in making vessels for domestic and industrial purposes. When rolled very thin, it forms tin-foil used in wrapping tobacco, etc.; but on account of the cost of the metal, tin-foil is replaced by lead-foil whenever possible. Tin readily forms alloys with other metals, furnishing brass, bronze, britannia metal, pewter, solder, white bearing metal, etc. "Tin" articles are now made largely from sheet iron or rather mild steel coated with a layer of tin. The layer of tin protects the iron from oxidation, although once the layer of tin is broken through, oxidation goes on rapidly. Tin-amalgam is used in making mirrors. Tin condensers are used for laboratory stills. L. T. Sherwood and G. Alleman [18] employed a tin cathode in place of platinum for the electrodeposition of zinc, copper, silver, cadmium, and nickel. Tin in conjunction with an acid is used as a reducing agent. C. Willgerodt, and A. G. Page discussed its use as a catalytic agent in chlorinations— the former obtained favourable, the latter unfavourable, results. Stannic oxide is used as a polishing powder, and as an opacifying agent in glasses, glazes, and enamels; tin sulphide or mosaic gold is used as a bronzing powder, and the two chlorides are used as a mordant, in weighting silk, and in dyeing.

The atomic weight of tin.—There was some doubt about the eq. of tin at the beginning of the nineteenth century. J. Dalton [19] represented the at. wt. by 50 when $O=7$, *i.e.* 57 when $O=8$. In 1812 J. J. Berzelius regarded the eq. as 118 when that of oxygen is 8, and he represented the formulæ of the two oxides SnO_2 and SnO_4, and. titanic oxide was represented TiO_4. J. L. G. Meinecke used 36 (oxygen, 8); C. G. Bischoff, 117·6 (O, 8); and T. Thomson, 60 (O, 8). This must have been somewhat disquieting. In 1826, J. J. Berzelius halved the eq. he employed in 1812, and obtained 59 (O, 8). He therefore represented the formulæ of stannous oxide, SnO, and stannic oxide, SnO_2, the same as is done to-day. The same year, J. B. A. Dumas measured the vap. density of *spiritus fumans Libavii*, and although he obtained a value in agreement with the formula $SnCl_4$, he unfortunately assumed that the at. wt. of tin is represented by that quantity of tin which unites with two vols. of chlorine to form tin perchloride. This made the eq. of tin 29·5 when that of oxygen is 8, and the formulæ of stannic oxide and chloride were respectively SnO and $SnCl_2$, and those of stannous oxide and chloride respectively Sn_2O and SnCl. In the same year, 1826, L. Gmelin employed 59 (O, 8). P. T. Meissner, 1834, O. B. Kühn, 1837, and P. F. Cauchy, 1838, represented the eq. of tin by 58·8 or 58·9 (O, 8). Accordingly, if the at. wt. of oxygen be 16, the at. wt. of tin will approximate 118; and tin will be quadrivalent in the stannic compounds and bivalent in the stannous compounds. This is in harmony with Avogadro's law applied to the volatile compounds of tin, and with the extension of that law to soln. It also fits in very well with the sp. ht. rule; and with the law of isomorphism applied to the oxides and the complex fluorides of tin, titanium, and zirconium. With this value for tin, the element fits very well in the periodic table as a member of the silicon family of elements.

The at. wt. of tin has been calculated from the ratio $Sn : SnO_2$ obtained by treating tin with nitric acid and igniting the product; or else by roasting the metal; thus, with $O=16$, J. L. Gay Lussac obtained 117·65; J. J. Berzelius, 117·65–118·08; G. J. Mulder, 116·30–117·00; C. L. Vlandeeren and G. J. Mulder, 118·16; J. B. A. Dumas, 118·06; J. D. van der Plaats, 118·09; J. Bongartz and A. Classen, 119·34; and F. W. Schmidt, 118·5. B. Brauner and H. Krepelka said that the oxidation of tin by nitric acid is useless because of the adsorbed products in the metastannic acid. It yields by simple calcination $Sn : SnO_2$, 118·02; and this is raised to 118·66 when the stannic oxide is fused with potassium hydrosulphate. J. D. van der Plaats also reduced stannic oxide with hydrogen, and from the ratio

$SnO_2 : O$ obtained 118·07. J. B. A. Dumas obtained 117·98 from the ratio $SnCl_4 : 4Ag$. B. Brauner and H. Krepelka obtained 118·7 from the ratio $SnBr_4 : 4Ag$; and H. Krepelka, 118·699. J. Bongartz and A. Classen electrolyzed a soln. of ammonium chlorostannate in one of ammonium oxalate, and from the ratio $(NH_4)_2SnCl_6 : Sn$ obtained 119·09 (O, 16); and by similarly treating potassium chlorostannate, they obtained 119·07 from the ratio $K_2SnCl_6 : Sn$. B. Brauner and H. Krepelka said that the electrolysis of ammonium chlorostannate is useless because of the difficulties involved in completely reducing the cathode deposit. This makes the result too high. J. Bongartz and A. Classen also electrolyzed a soln. of stannic bromide in one of ammonium oxalate, and from the ratio $SnBr_4 : Sn$, they calculated 118·97. G. P. Baxter and H. W. Starkweather electrolyzed a soln. of stannic chloride in $0·3N$-HCl, and from the ratio $SnCl_4 : Sn$ computed 118·703. J. Bongartz and A. Classen also converted tin into stannic sulphide, separated the sulphur and weighed it as barium sulphate. From the ratios $Sn : SnS_2 : 2BaSO_4$, they obtained 119·08. A. L. Bernoulli computed 119·46 from physical data. Calculations of the best representative values from the observed data were made by L. Meyer and K. Seubert, and W. Ostwald. F. W. Clarke gave 119·057; and B. Brauner, 119·05. The International Table gave 118·70 for the best representative value in 1925.

A. Jouniaux inferred from the latent heat, and from the effect of tin on the f.p. of other metals, that above 630°, the mol. of tin is monatomic; and that about 115°, the mol. is triatomic. He also inferred that the mol. is probably complex when associated with lead, and simple when associated with cadmium and zinc.

The **atomic number** of tin is 50. F. W. Aston [20] found that the positive-ray analysis of tin tetramethyl gave eight **isotopes** for tin, with the respective at. wts. 116, 117, 118, 119, 120, 121, 122, and 124. The differences between these values are integral to the degree of accuracy attainable, which is 1 in 1000. A. S. Russell, H. Collins, and F. H. Loring discussed this subject. A. L. Narayan found the results did not agree with J. C. McLennan's view that the spectral displacement of the isotopes is given by the at. number multiplied by the displacement calculated from the assumed structure of the atom. E. Rutherford and J. Chadwick found no sign of **atomic disintegration** as evidenced by the emission of long-range particles when tin was bombarded by a-rays; but H. Pettersson and G. Kirsch were able to disrupt the atoms. J. Beckenkamp, and H. G. Grimm and A. Sommerfeld studied the electronic structure of tin.

§ 6. The Alloys of Tin with the Alkali Metals

W. Guertler[1] studied the affinity of tin for the metals generally. P. Lebeau made a tin-lithium alloy by the electrolysis of a mixture of potassium and lithium chlorides, using a tin cathode. J. L. Gay Lussac and L. J. Thénard found that a mixture of 7 vols. of tin-filings to 2 vols. of potassium united with slight incandescence, forming a fusible, brittle alloy which exhibited a fine-grained fracture ; oxidized quickly in air ; and effervesced when treated with water. If a larger proportion of potassium be employed, the alloy takes fire when pulverized in air. According to G. S. Sérullas, when granulated tin is heated with potassium tartrate, or if stannic oxide be heated with charred

potassium tartrate, and carbon, a pyrophoric alloy is formed] which evolves hydrogen slowly when in contact with water. G. Bredig and F. Haber obtained the alloy by the disintegration of the metal electrode in electrolysis, by an alternating current; P. Lebeau, by the method used for the lithium alloys. C. T. J. Vautin described the preparation of alloys of tin with the alkali metals by electrolysis. According to D. P. Smith, the two elements are miscible in all proportions in the fused state; and most of the alloys melt at a temp. higher than the m.p. of the components. The alloys rapidly attack glass and even steel, so that the results of the thermal analysis, indicated in Fig. 29, were not very conclusive. Evidence was obtained of the existence of **potassium monostannide**, KSn; **potassium hemistannide**, K_2Sn; **potassium distannide**, KSn_2, with a transition point at 413°; and of **potassium tetrastannide**, KSn_4. F. W. Bergstrom observed a break in the solubility curve of tin in a soln. of potassium amide in liquid ammonia, corresponding with K_4Sn_8 or KSn_2. G. Tammann studied the electrode potential and chemical properties of these alloys; and R. Kremann and E. Pressfreund found evidence of K_2Sn, KSn_2, KSn_4, and possibly KSn, in their measurements of the electromotive behaviour of these alloys.

FIG. 29.—Equilibrium Curves of the Potassium-Tin Alloys.

J. L. Gay Lussac and L. J. Thénard prepared an alloy of tin with sodium by a process analogous to that which they employed for the potassium alloy; G. S. Sérullas obtained the alloy by heating a mixture of tin with charred soap; and C. Löwig, and H. Caron, emphasized the need for the exclusion of air. C. T. Heycock and F. H. Neville found that the f.p. of tin was raised 11·61° by adding 4·57 at. per cent. of sodium. A. Weiller made an alloy of the two metals on a large scale; C. T. J. Vautin made it electrolytically; and C. Bredig and F. Haber, by the process indicated above. H. Bailey melted tin with an excess of sodium, and heated the product in a closed crucible and obtained a tin-sodium alloy approximating **sodium hemistannide**, Na_2Sn. W. Hume-Rothery said that the crystals show octahedral cleavage. W. Biltz and W. Holverscheit gave 12 Cals. for the heat of formation; 45 Cals. for the heat of oxidation; 3·111 for the sp. gr. at 25°, and 52·9 for the mol. vol. when the additive rule gave 63·7. P. Lebeau separated **sodium tetritastannide**, Na_4Sn, by treating a sodium-tin alloy with liquid ammonia. C. A. Kraus and H. F. Kurtz observed the formation of the tetritastannide as an unstable compound in the reduction of tin salts by sodium amalgam. W. Biltz and W. Holverscheit gave 21 Cals. for the heat of formation; 47 Cals. for the heat of oxidation; 2·315 for the sp. gr. at 25°, and 91·0 for the mol. vol. when the additive rule gave 111·1. C. H. Mathewson made a thermal analysis of the tin-sodium alloys. The m.p. curve consists of six branches, Fig. 30. There are two well-marked maxima at 477° and 27·92 per cent. of sodium, and 576° and 16·23 per cent. of sodium respectively. Five distinct compounds of tin and sodium exist, namely: (1) sodium tetritastannide, Na_4Sn, which at 405° undergoes transformation according to the equation $Na_4Sn \rightleftharpoons 0.091Na_2Sn + $ fused alloy (3·82 mols $Na + 0.91$ mol Sn). F. Paneth and co-workers found that this alloy gave no iron

FIG. 30.—Equilibrium Curves of the Sodium-Tin Alloys.

hydride when treated with acids. (2) Sodium hemistannide, Na_2Sn, which, according to C. H. Mathewson, has a m.p. of 477°, and, according to W. Hume-Rothery, 470°. (3) **Sodium tritetritastannide**, Na_4Sn_3, is the hardest and most brittle of the five compounds. At 478°, it melts with transformation according to

the equation $Na_4Sn_3 \rightleftharpoons 0.375NaSn + fused$ alloy (3·62 mols Na + 2·62 mols Sn). It occurs in two crystalline modifications, a and β; the transformation of the β- into a-crystals is attended by a considerable increase of vol. W. Biltz and W. Holverscheit gave 36 Cals. for the heat of formation; 43 Cals. for the heat of oxidation; 3·570 for the sp. gr. at 25°; and 125·6 for the mol. vol. when the additive rule gave 143·7. (4) According to C. H. Mathewson, **sodium mono-stannide,** NaSn, with a m.p. of 576° undergoes, at 483°, a polymorphic transformation. W. Biltz and W. Holverscheit gave 11 Cals. for the heat of formation of the monostannide; 42 Cals. for the heat of oxidation; 3·990 for the sp. gr. at 25°, and 35·5 for the mol. vol. when the additive rule gives 40·0 Cals. (5) **Sodium distannide,** $NaSn_2$, is the softest and toughest of the five compounds, and, like NaSn, has the appearance of tin. F. W. Bergstrom found a break in the solubility curve of tin in a soln. of sodium amide in liquid ammonia, corresponding with Na_4Sn_8 or $NaSn_2$. W. Biltz and W. Holverscheit found that at 305°, it undergoes transformation in accordance with the equation $NaSn_2 \rightleftharpoons 0.667NaSn$ + fused alloy (0·333 mol Na + 1·333 mols Sn); they gave 15 Cals. for the heat of formation of distannide; 39 Cals. for the heat of oxidation; 4·725 for the sp. gr.; and 55·1 for the mol. vol. when the additive rule gives 56·3. According to C. H. Mathewson, a freshly cut surface of the tetrita- or hemi-stannide soon becomes covered in the air with a bronze film, but under vaseline, the surface of the former resembles that of tin, whilst the latter is steel-blue; the tritetri-tastannide shows a pale blue colour on a fresh surface; no film colour appears on oxidation. R. Kremann and J. Gmachl-Pammer found that the electrical conductivity curve showed singular points corresponding with Na_4Sn, Na_2Sn, NaSn, and $NaSn_2$. G. Tammann studied the electrode potential and chemical properties of these alloys; A. Battelli, the thermoelectric properties; and C. Vickers, the deoxidizing qualities for copper and bronze,

FIG. 31.—Equilibrium Curves of Lithium-Tin Alloys.

G. Masing and G. Tammann[2] showed that lithium and tin form three compounds. The f.p. curves are indicated in Fig. 31. There is a maximum on the curve at 680°, representing **lithium tetritastannide,** Li_4Sn; a flat maximum at 465°, representing **lithium ditritastannide,** Li_3Sn_2; and an unstable compound, **lithium hemipentastannide,** Li_2Sn_5, reacting with the melt at 320°.

§ 7. The Alloys of Tin and Copper

The term **bronze** is applied to the alloys of copper and tin, although alloys with proportions of these two elements within more or less ill-defined ranges may receive specific names, *vide infra*. The Alloy Committee [1] recommended that the term bronze be reserved for copper-tin alloys containing over 50 per cent. of copper ; and that the presence of one or more metals, intentionally added, be denoted by a prefix—*e.g.* an alloy with 1 per cent. of zinc, 29 per cent. of tin, and 70 per cent. of copper would be a *zinc-bronze*. If additional metals be present they can be indicated in a similar way, or the term *complex bronze* may be used when it is not necessary to mention the other elements specifically. The history of bronze has been discussed in connection with copper, **3**. 21, 1 ; and brass, **4**. 30, 21. A large number of analyses of ancient bronzes from different countries, and of Chinese and Japanese art-bronzes, have been reported.[2] The bronzes made by the ancients varied considerably in the proportion of tin and copper employed. Other ingredients were added purposely, or occurred as accidental impurities from the use of complex ores. The ancients made instruments of various kinds from these alloys, and weapons of war and of chase of great strength, with a keen cutting edge, and harder than iron—rivalling steel.

The presence of tin hardens the copper, and the resulting alloy can take a high polish, its m.p. is comparatively low, and when melted, it can be cast very well. The addition of a small proportion of tin to copper, however, prevents the product rolling well when hot, and if more tin is used, the alloy is not malleable when cold. Bronze is tempered by heating it to the required temp., and rapidly cooling in water ; this is the reverse of the process employed in tempering steel. Modern bronzes are rarely simple binary alloys ; and are usually ternary or quaternary. Sometimes even more constituents are added. Among the commercial varieties of bronze are the so-called **gun-metals,** which were formerly much employed in the construction of ordnance. Each country seems to have preferred a mixture of its own which usually varied from 8–11 parts of copper to one of tin. The typical alloy is 90 : 10. The thermal history of the alloy is almost as important as a knowledge of its chemical composition. The modern gun-metals are frequently ternary alloys containing zinc, as well as copper and tin, and are sometimes grouped with the so-called *machine-brasses*. These alloys are employed for different parts of machinery, *e.g.* the bearings and parts subjected to great friction. They are also employed for parts of pumps, propeller blades and boxes, mechanical instruments, etc.

J. A. Phillips emphasized as special characteristics of **phosphor-bronze :**

Its freedom from corrosion by salt water, which is apparently largely due to its freedom from zinc ; its high qualities as a mechanical constructive material as compared with an ordinary zinc-free bronze ; the small effect which a rise of temp. has upon its mechanical properties, which remain practically unimpaired at temp. at which zinc copper alloys exhibit serious drops in strength ; and the fact that a spark cannot be readily obtained from it by a blow. Phosphor-bronzes of high phosphorus content possess low friction coefficients for most metals, and are hard enough to resist abrasion well.

The properties of these alloys were described by H. Behrens,[3] X. Müller, E. Priwoznik, J. B. Grief, W. Hampe, E. S. Sperry, W. C. Roberts-Austen, H. Morin, S. Kalischer, E. J. Maumené, etc. The subject is discussed in A. H. Hiorns, *Mixed Metals or Metallic Alloys* (London, 1901) ; W. T. Brannt, *The Metallic Alloys* (Philadelphia, 1908). Alloys of copper and tin with a small quantity of phosphorus and maybe other elements are called **phosphor-bronzes.** They are used for making tubes, wire-ropes, springs, screws, pinions, valves, steam and boiler fittings, pumps, axle-bearings, bushes, cog-wheels, parts of machinery exposed to great friction, ornamental castings, etc. In 1848, A. and H. Parkes

patented the use of phosphorus in conjunction with copper, and brass; but they did not mention bronze. F. A. Abel described some results obtained with phosphorized copper; and H. de Ruolz and A. de Fontenay observed the great increase in tenacity and resistance to abrasion obtained by adding phosphorus to bronze, and C. Künzel and co-workers demonstrated the improvement in the mechanical properties of bronze to which a little phosphorus had been added. The proportion of phosphorus rarely exceeds 1 per cent., and if upwards of 4 per cent. be present, the alloy is considered to be useless. E. S. Sperry said that if the phosphor-bronze is to be rolled it should have no more than 0·5 per cent. of phosphorus and no zinc. A. Phillips reported nearly 100 analyses of commercial phosphor-bronzes, and in these the copper ranged from 82·3–97·1 per cent.; tin from 2·2–14·5 per cent.; lead in seven samples up to 6·23 per cent; zinc, in six samples up to 2·74 per cent.; and phosphorus up to 1·56 per cent. Analyses have been reported by J. Bayschinger and K. Stölzel, E. Priwoznik, A. Ledebur, C. Künzel, etc. Phosphor-bronze resists the corrosive action of sea-water better than copper; and mine-water, better than iron or steel. A. Weiller devised an alloy of copper, tin, and silicon, called **silicon bronze,** said to be specially adapted for telegraphic and telephonic purposes, since its electrical conductivity is much higher than that of phosphor-bronze. The alloys used in the manufacture of bells—**bell-metals**—usually contain copper, 74–85 per cent.; tin, 15–26 per cent. Other proportions are used to produce different sounds, and other metals—zinc, iron, lead, bismuth, silver, antimony, or manganese—may be added either for cheapness or to produce a special tone. The typical alloy is 80 : 20. The sound from brass bells is of inferior quality. In some of the white table bells, tin is the dominant component. Some white alloys, usually approximating Cu_4Sn, admit of a brilliant polish, and were formerly much used for mirrors, and hence were called **speculum metals.** They are now sometimes used in the construction of mirrors for optical instruments. Their composition ranges from 30–34 per cent. tin, and 62–69 per cent. copper. In some cases lead, zinc, arsenic, silver, nickel, or antimony has been added. The typical alloy is 70 : 30. The term **art-bronzes** is applied to alloys which are employed for statuary, vases, and ornaments of various kinds. In a number of statues, the proportion of copper ranges from 72–91 per cent.; tin, 0·14–10·2 per cent.; zinc, 0·1–26 per cent.; lead, up to 3 per cent.—small proportions of iron, nickel, and antimony may also be present.

According to A. F. Gehlen,[4] if the two elements, tin and copper, are simply fused together, bronze is produced; if the mixture be not stirred, two liquid layers containing very different proportions of the two elements are formed. The combination is attended without the production of light or heat. A similar result was obtained by C. J. B. Karsten, C. Bischoff, A. Guettier, and W. Campbell with molten tin. Segregation phenomena were studied by O. Bauer and H. Arnd, and G. Masing. Bronze is usually manufactured by melting a charge of say 90 lbs. in fireclay or plumbago crucibles; and for large castings, a reverberatory furnace or a large number of crucibles is employed. The copper is well melted and kept in fusion some time before the tin is added. The oxidation which occurs during the melting removes 3 or 4 parts of copper to one of tin, and due allowance must be made for this loss. H. S. Primrose has discussed the preparation of gun-metal; and F. W. Rowe, the effect of the casting temp. on the metal. In preparing small samples, and to avoid oxidation losses, E. S. Shepherd and G. B. Upton added tin to molten copper in an atm. of coal-gas. Other methods were used by A. P. Laurie, A. Saxer, H. Behrens, and A. Sentex and co-workers. E. Lenssen showed that if a little cupric salt be added to a not too conc. soln. of stannous oxide in alkali-lye, a black flocculent precipitate is formed which acquires a yellow metallic lustre under the burnishing-tool, and consists of a tin-copper alloy mixed with some cuprous and stannous oxides. W. Spring said that the alloy is formed when a mixture of powdered tin and copper is subjected to a high press.—*vide* 1. 13, 18. H. Wiess studied the mutual diffusion of copper

and tin. B. E. Curry obtained the alloy electrolytically from a soln. of salts of copper and tin, oxalic acid, and ammonium oxalate. A current density of 0·2–0·3 amps. was used and a rotating anode. Tartrates were not satisfactory. C. H. Proctor used a bath of a soln. containing the two metal sulphides, an alkali sulphide, and potassium cyanide ; C. Langbein used a soln. of cupric phosphate, stannous chloride, and sodium pyrophosphate ; C. de la Salzede, a soln. of cupric and stannous chlorides, potassium carbonate and cyanide, but C. Langbein said only tin is deposited from this soln. G. Ongaro, S. Ledermann, F. Förster, F. C. Mathers and S. Sowder, R. Kremann and co-workers, W. D. Treadwell and E. Beckh, studied the conditions for the simultaneous electrodeposition of tin and copper.

The equilibrium diagram for the bronzes, the copper-tin alloys, represents one of the most complicated binary systems known. All parts are not yet known with certainty. H. le Chatelier,[5] W. C. Roberts-Austen and E. Stansfield, and C. T. Heycock and F. H. Neville studied the f.p. curves of the alloys, and in 1903, the last-named investigators gave an exploration covering the whole field. The plan so prepared has served as a guide for subsequent workers. As a result of the work of E. S. Shepherd and co-workers, S. L. Hoyt, J. E. Outerbridge, E. Heyn,
FIG. 32.—Equilibrium Diagram of the Copper-Tin Alloys.

F. Giolitti and G. Tavanti, W. Guertler, H. Endo, D. Stockdale, K. Honda and T. Ishigaki, and J. L. Haughton, modifications of specific portions of the plan have been made. The observations of O. Bauer and O. Vollenbruck are summarized in Fig. 32.

The area I represents a solid soln. of tin in copper, *i.e.* α-bronze. W. Guertler proposed to call it *kuprite*. The conc. of the tin varies with temp. and, according to W. Guertler, E. S. Shepherd and E. Blough, and O. Bauer and O. Vollenbruck, may reach a maximum of about 13 per cent. ; W. Broniewsky said 10 per cent. Area II represents the region where the α-crystals are stable in contact with the molten alloy ; III, mixed crystals of α- and β-bronze ; IV, mixed crystals of α+(α+γ) bronze, and V, mixed crystals of γ+(α+γ) bronze ; VI, mixed crystals of α+(α+δ) bronze ; and XIII, mixed crystals of δ+(α+δ)

bronze.   On account of the analogy of the $a+\delta$ area—VI and XIII—with the pearlite of steel, W. Guertler proposed to call it *bronzite*.   Area VII represents β-crystals stable in contact with the molten alloy; VIII, homogeneous crystals of yellow β-bronze; IX, homogeneous crystals of white γ-bronze; X, mixed crystals of β- and γ-bronzes; XI, mixed crystals of β- and γ-bronzes; XII, mixed crystals of δ- and γ-bronzes; XIII, *vide supra*; XIV, mixed crystals of δ- and ϵ-bronzes; XV, ζ-bronze stable in contact with the molten alloy; XVI, homogeneous ζ-bronze; XVII, mixed crystals of η- and ζ-bronzes; XVIII, homogeneous η-bronzes; XIX, η-bronze stable in contact with the molten alloy; XX, mixed crystals of η- and θ-bronzes; XXI, mixed crystals of η- and θ'-bronzes; XXII, θ-bronze stable in contact with the molten alloy; XXIII, homogeneous θ-bronze; XXIV, homogeneous θ'-bronze; XXV, mixed crystals of θ- and ι-bronzes; XXVI, mixed crystals of θ'- and ι-bronzes; XXVII, ι-bronze stable in contact with the molten alloy; and XXVIII, ι-bronze, *i.e.* a solid soln. of copper in tin.

The eutectic at 228° has about 98 per cent. of tin.   Evidence for the existence of the polymorphic transformation of tin in the copper-tin alloys at 161° is wanting. It probably occurs rather lower than with pure tin owing to the presence of a small proportion of dissolved copper.   The regions corresponding with the allotropic changes of tin are represented by dotted lines to show that they have not yet been observed.

The part played by the phosphorus was discussed by M. Beuling, and H. Behrens, etc.   J. T. Milton thus described the freezing of ordinary gun-metal, $Cu : Sn = 9 : 1$.

The first portions to solidify are richer in copper than the average.   These separate out in skeleton form, the skeleton portions in the space ultimately forming one crystal, arrange themselves with a certain degree of parallelism; that is to say, with the same orientation.   These skeleton forms are nuclei on which more solid separates out, containing rather less copper than before, and therefore rather more tin, but still richer in copper than the average of the metal.   On these, in turn, a further deposition of metal still poorer in copper and richer in tin takes place, the skeleton forms meanwhile becoming gradually thicker and thicker, with less intervening spaces between them.   The metal remaining liquid gradually becomes richer in tin, until at last, if there is sufficient tin in the crystal, a kind of eutectic, much richer in tin than the average of the metal, fills up all the interspaces.   When gun-metal is broken at a red heat this structure is revealed, but it can also be seen when the metal is polished and suitably etched.

Only one compound, **copper tritastannide,** Cu_3Sn, is shown on the equilibrium diagram, Fig. 32.   Analyses, etc., were made by F. Mylius and O. Fromm; H. le Chatelier, A. P. Laurie, and C. T. Heycock and F. H. Neville,   H. le Chatelier said that it can be obtained by treating an alloy of tin and copper (2 : 1) with conc. hydrochloric acid; and C. T. Heycock and F. H. Neville, by heating an alloy with 38–70 at. per cent. of tin for 72 hrs. at 454°, and quenching.   The product treated with conc. hydrochloric acid at 30° furnishes a dark grey residue of this compound.   A. P. Laurie, O. Bauer and O. Vollenbruck, F. Mylius and O. Fromm, F. Förster, H. Behrens, E. J. Ball, and A. Riche also reported this compound. It appears as bluish-grey or bluish-white lamellæ.   O. Bauer and O. Vollenbruck say that it exists in two modifications, an a-form stable up to 676°, and a stable β-form which melts unchanged at 720°.   K. Bornemann and F. Sauerwald, and H. Alterthum found 23 per cent. dissociation at 900° and 16 per cent. at 1200°. The tritastannide is but slowly attacked by hydrochloric acid, and is fairly stable towards acids generally.   Hot conc. hydrochloric acid was found by F. Mylius and O. Fromm to decompose it more rapidly.   O. Sackur and H. Pick gave 0·45 volt for the potential against zinc; and N. A. Puschin, 0·50 volt.   A. W. Smith has shown that the different physical properties agree with the existence of copper tritastannide.   K. Bornemann and F. Sauerwald found only one break in the sp. gr. curve of molten copper-tin alloys; and this is taken to show that this is the only compound of these elements stable in the liquid.   G. Tammann and M. Hansen found the binary alloys of Cu_3Zn_3 and Cu_3Sn have the typical V-curve with the eutectic at about 700° and 18 per cent. Cu_3Sn.

Observations on many of the physical properties of the various copper-tin alloys give curves with singular points sometimes attributed to the presence of definite com-

pounds, but such evidence is not adequate and sufficient. Thus, C. T. Heycock and F. H. Neville, W. C. Roberts-Austen, E. J. Ball, A. Riche, R. Ledoux, H. Behrens, and W. Guertler, suggested the possibility of the existence of **copper tetritastannide**, Cu_4Sn, and O. Bauer and O. Vollenbruck consider that they were able definitely to prove its existence. G. Tammann and M. Hansen found that the binary alloys of Cu_4Sn and Cu_2Zn_3 have the V-shaped f.p. curve with the eutectic at 725° and 63 per cent. of Cu_4Sn. P. Braesco also obtained evidence of the existence of the tetritastannide. A. Riche, N. A. Puschin, and O. Sackur and H. Pick reported *copper hemistannide*, Cu_2Sn ; A. Riche, and F. Förster, *tin cupride*, or *copper monostannide*, CuSn; W. H. Miller, and R. Roth, *copper distannide*, Sn_2Cu; C. F. Rammelsberg, *copper tritaheptastannide*, Sn_7Cu_3; A. Riche, *copper tristannide*, Sn_3Cu, and *copper pentastannide*, Sn_5Cu. H. Moissan and J. P. O'Farrelly found that the alloy with a constant composition when boiled in the electric furnace corresponds with CuSn. J. E. Stead held that the crystallites which separated from alloys rich in tin were composed of SnCu, and not $SnCu_3$, and that the crystallites obtained by dissolving away the excess of tin in dil. acid from alloys with between 3 and 34 per cent. copper consist of two definite constituents—one covering the other. The one crystallizing out first contains most copper, and the second constituent, probably SnCu, crystallizes on the surface of this. H. le Chatelier said that neither Cu_4Sn nor Cu_2Sn exists as a chemical individual. R. Ledoux found no evidence of CuSn. O. Bauer and O. Vollenbruck reported *copper pentahexitastannide*, Cu_5Sn_6, which they isolated from alloys with over 60 per cent. of tin. It is stable below the eutectic at 225° in all alloys with over 61 per cent. of tin.

According to R. Mallet,[6] the **colour** of the copper-tin alloys containing 82·81–84·29 per cent. of copper is reddish-yellow; with 78·97–81·10 per cent., yellowish-red; with 72·80–76·29 per cent., pale red; with 68·21 per cent., ash-grey; 61·69 per cent., dark grey; with 51·75 per cent., greyish-white; 34·92 per cent. white, becoming still whiter with increasing proportions of tin. Observations were made by H. Behrens, C. Bischoff, E. S. Shepherd, and F. J. Otto. M. Chikashige examined the effect of a beam of light reflected four times from the surface of bronze. Starting with copper, the exposure to the multi-reflected red ray required to produce equal blackness on a panchromatic plate, increased with the proportion of tin until 35 per cent. of tin was present, when the alloy contained ε-bronze and tin tricupride, which is nearly white. The exposure then diminished to the tin end of the series. The intensity of reflection is greatest with the hardest alloys which take the best polish. C. F. Rammelsberg, and W. Miller discussed the form of the **crystals** of copper-tin alloys. E. C. Bain studied the X-radiograms. According to E. Heyn and O. Bauer, the **fracture** of alloys which have been cooled rapidly have a uniform colour, but if slowly cooled, there may be grey and yellow flecks. R. Mallet, and J. Rieffel found that the fracture of alloys with 84·29–81·10 per cent. of copper is fine-grained; with 78·97 per cent., vitreous and conchoidal; with 76·29 per cent., vitreous; with 72·80–68·21 per cent., conchoidal; with 61·69 per cent., lamellar and granular; with 51·75 per cent., vitreous and conchoidal; with 34·92 per cent., lamellar and granular; with 21·15–15·17 per cent., vitreous and granular; with 11·82 per cent., vitreous and lamellar; and with 9·68 per cent., earthy. H. Behrens said that the alloy with 15–25 per cent. of tin is fine-grained; and with 25–40 per cent. of tin, conchoidal. The effect of annealing on the physical properties of bronze has been discussed by C. H. Mathewson,[7] H. S. Rawdon, W. Wyss, J. S. G. Primrose, L. Grenet, C. F. Smart, O. Smalley, R. J. Anderson and C. H. Eldridge, etc.; and P. G. J. Gueterbock and G. N. Nicklin, the effect of copper as an impurity on the physical properties of tin. G. H. Gulliver calculated the difference in the relative proportions of solid and liquid between the liquidus and solidus curves for very slow and rapid cooling. A. M. Portevin found **Widman-stätten figures** developed on some copper-tin alloys; and he studied the structure of the eutectic. A. Westgren and G. Phragmen studied the **X-radiograms** of these alloys.

Observations on the **specific gravity** of the tin-copper alloys have been made by J. H. Croockewit,[8] C. Bischoff, R. H. Thurston, G. Kamensky, A. L. Norbury, R. Mallet, A. Riche, S. L. Kneass, E. von Maey, T. Turner and J. L. Haughton, K. Bornemann and F. Sauerwald, J. Rieffel, E. S. Shepherd and E. Blough, and F. C. Calvert and R. Johnson. The subject has been examined in some detail

by H. Heape, and the results with chill casting and sand casting are plotted in Fig. 33. The following is a selection from the observed data :

Cu	.	5·45	22·30	30·10	48·72	59·90	79·66	90·06	97·73* per cent.
Chill	.	7·389	775·4	8·008	8·498	8·839	8·802	8·752	8·833
Sand	.	7·408	7·734	7·989	8·382	8·669	8·716	8·704	8·712

There is a difficulty in obtaining sound castings for these determinations. C. Bischoff noted that quenching decreased the sp. gr. of the alloys. The differences in the two types of cast bronze illustrate the effect of casting on the result. H. Heape found that except for a small portion of the sand-cast curve, both curves lie above the admixture rule in which it is assumed that the alloying occurs without change of vol. This means that there is a contraction due to the alloying, and this with the subsequent contraction which occurs during solidification, produces a decrease in vol. as the resultant effect with all alloys. The chill-cast alloy has invariably a higher sp. gr. than those for the sand-cast specimens except in the case of those with about 5 per cent. of copper. The zero point with alloys containing 8 per cent. of copper corresponds with the points of zero expansion observed by T. Turner and J. L. Haughton. R. Mallet's curve had a maximum with 76 per cent. copper, and a minimum with 20 per cent. copper ; A. Riche's curve had a maximum with 61 per cent. copper, and a small dip with 10 per cent. of copper. T. Turner and J. L. Haughton's curve had a maximum with about 70 per cent. of copper ; E. von Maey's curve, K. Börnemann and F. Sauerwald's curve had a maximum near 60 per cent. of copper. H. Heape did not get the maximum with 60 per cent. of copper, but expansions occur with 99, 55, and 20 per cent. of copper. There is no confirmation of an expansion with 70 per cent. of copper, though there is one with 35 per cent. of copper. E. von Maey gave for the **specific volumes** :

FIG. 33.—The Specific Gravity of Cu–Sn Alloys.

Sn	.	.	0	5·6	9·0	25	28	39·2	56	70·3	10Q per cent.
Sp. vol.	.	.	0·1121	0·1139	0·1142	0·1132	0·1123	0·1113	0·1197	0·1254	0·1374

C. Schmidt attempted to calculate the composition from the sp. gr. of the alloy. K. Bornemann and F. Sauerwald found the sp. gr. of molten copper-tin alloys, and there is only one break in the curve corresponding with the tricupride, which thus appears to be the only compound stable in the liquid state. A. L. Norbury estimated the sp. vol. of the solute atoms of tin in copper. J. H. Chamberlain found that when some alloys of copper and tin are heated, there is a small contraction ; thus, between 700° and 760°, a bar with 89·6 per cent. copper contracted 0·012 cm. ; one with 91 per cent. copper, 0·0045 cm. ; and one with 89·7 per cent. copper, 0·00015 cm. It is assumed that an expansion is produced in casting the bars owing to the chilling of the liquid soln. between the dendrites of the α-solid soln. ; and on heating, there is a more complete soln. of the α-crystals which produces a greater homogeneity and causes a contraction in vol. P. Braesco studied the change in volume accompanying various transformations. E. A. Smith said that segregation nearly always takes place during the solidification of a plumbiferous bronze, but if nickel is present, the lead is not so liable to separate. G. Masing studied the changes in vol. during liquation.

The **hardness** of the copper-tin alloys was measured by H. Heape, A. Martens, F. C. Calvert and R. Johnson, J. Rieffel, P. Ludwik, H. le Chatelier, N. S. Kurnakoff and S. F. Schemtschuschny, H. S. and J. S. G. Primrose, O. Bauer and O. Vollenbruck, W. L. Kent, T. Matsuda, T. Matsuda and J. Shiba, A. Mallock, and T. Isihara. J. P. J. d'Arcet noted the decrease in the hardness of the copper-

tin alloys brought about by quenching. H. Behrens added that the presence of zinc or lead softened these alloys. The increased hardness conferred by a minute proportion of phosphorus was indicated by C. Montefiori-Levi and C. Künzel, M. Beuling, H. Behrens, F. von Friese, H. de Ruolz and H. de Fontenay, and A. Polain. The following values for the scleroscope hardness of sand-cast specimens were selected from data by T. Turner and J. L. Haughton. The curve, Fig. 34, represents :

Cu .	. .	4·0	29·4	41·0	60·7	62·6	72·7	80·4,	95·5 per cent.
Hardness		5	29	60	72	59	100	53	7

Brinell's hardness numbers for chill-cast and for sand-cast bronzes were measured by H. Heape, and the following is a selection from the observed data :

Cu	.	.	5·45	25·34	33·86	58·21	72·75	89·56	97·73 per cent.
Chill	.	.	8·9	26·8	39·0	95·4	182·6	41·0	29·7
Sand	.	.	7·6	13·9	21·5	50·3	166·2	31·2	27·9

D. Saito and K. Hayashi [9] tested the **fluidity** of molten bronzes for casting, and F. von Friese of phosphor-bronzes. G. Subrahmanian studied the viscosity, G. Tammann and K. Dahl, the plastic deformation, and O. Bauer and O. Vollenbruck, the **malleability** of bronzes at different temp. R. Mallet, R. Baumann, R. H. Thurston, A. Riche, L. Guillet, M. Beuling, H. Behrens, G. Wertheim, A. Guettier, B. E. Curry, W. D. Bancroft, O. Bauer and O. Vollenbruck, and C. T. Heycock and F. H. Neville measured the **tensile strength** of copper with different proportions of tin ; and R. H. Greaves and J. A. Jones, the notched bar **impact test**. J. P. J. d'Arcet found the tenacity and **ductility** is increased by quenching. L. Guillet quenched the bronze from 600°–800° and found the mechanical properties were improved ; and F. Giolitti and E. Pannain emphasized the importance of considering the rate of cooling on the mechanical properties. According to E. S. Shepherd and G. B. Upton, curve A, Figs. 35 and 36, refer to a bronze which has been held one week at 540° and water-quenched ; curve B, to a bronze tested as cast ; and curve C, to a bronze held one week at 400°, and furnace-cooled. They found that the tensile strength of bronzes consisting
FIG. 34.—The Hardness of the Cu–Sn Alloys.
FIG. 35.—Tensile Strength of Bronzes.
FIG. 36.—Ductility of Bronzes.

of pure α is affected but slightly by heat treatment. Bronzes containing 74–87 per cent. of copper are much stronger if annealed above the inversion temp. (510°) than if annealed below. Prolonged annealing tends to coarsen the crystalline structure, to decrease the tensile strength, and to increase the ductility. The tin-rich crystals are stronger than those low in tin. The strongest bronzes, containing 78–81 per cent. copper, annealed below 510°, consist of mixtures of α and δ crystals. Bronzes containing no α crystals have very low tensile strengths. When tested as cast, the ductility of bronzes decreases with decreasing copper content. The ductility of cast bronzes can be increased about 5 per cent. by bringing to a

red-heat, and then quenching in water. With bronzes containing less than 88 per cent. of copper, this treatment increases the strength markedly. Annealing at 540° for one week, causes an enormous increase in the ductility, especially of bronzes containing 88–90 per cent. of copper. Annealing the 85–90 per cent. copper bronzes at 400° for one week causes an effect on ductility similar to, but less than that due to, annealing for the same time at 540°. It is possible to make a cast bronze with an ultimate tensile strength of over 60,000 lbs. per sq. in. and an ultimate elongation of about 1·5 per cent., or a bronze with an ultimate tensile strength of 45,000 lbs. per sq. in. and an ultimate elongation of 39 per cent. By suitable heat treatment, it is possible to vary the ultimate elongation of a bronze containing 90 per cent. copper from 10 per cent. to 37 per cent. without affecting the tensile strength materially. The bronzes have no maximum load in the sense that iron and steel have. The ultimate **resilience** of bronzes containing more than 95 per cent. of copper is low because the breaking strengths are low. With bronzes containing less than 85 per cent. of copper, the resilience is low because the elongation is small. The maximum resilience occurs between 90 per cent. and 87 per cent. of copper ; it is some 15 per cent. higher than that of the wrought-iron curve. A. Philip reported on about a hundred samples of commercial phosphor-bronze and found the tensile strength to range from 7·76 to 46·04 tons per sq. in. ; and the percentage elongation on 2 ins., to range from 1 to 59 ins. The improved mechanical properties of phosphor-bronze over ordinary bronzes was indicated by C. Montefiori-Levi and C. Künzel, J. Arnott, J. Kiewit, R. T. Rolfe, C. B. Dudley, R. Jenny and co-workers, J. Bauschinger and K. Stölzel, A. Philip, M. Beuling, etc. A. K. Huntington, F. C. Lea, C. P. Karr, H. S. Gulick, and J. C. Longbottom and A. Campion measured the effect of temp. on the mechanical properties of gun-metal. The first-named used an alloy with 97·673 per cent. copper ; 2·408 per cent. tin ; and 0·024 per cent. lead ; and found the results indicated in Table V. H. S. and J. S. G. Primrose measured the influence of the

TABLE V.—TENSILE STRENGTH OF BRONZE AT DIFFERENT TEMPERATURES.

Temp.	Yield in tons per sq. in.	Breaking load in tons per sq. in.	Elongation per cent. in 2 ins.	Reduction area per cent.
15·5	4·83	19·13	56·0	75·0
204·0	2·84	16·77	53·0	68·6
260·0	2·84	16·25	45·0	56·4
316·0	2·84	14·54	23·5	26·0
371·0	2·55	11·36	21·0	22·5
427·0	3·12	12·97	36·5	29·4
465·0	2·84	12·31	38·5	42·2

quenching temp. of gun-metal on the tensile strength (tons per sq. in.) and found :

	—	500°	600°	700°	800°
Tensile strength	15·6	8·2	6·5	4·9	9·0
Elongation per cent.	28·0	12·0	7·5	3·0	5·5

With chilled castings the effects of annealing for 30 mins. at different temp. were :

	—	500°	600°	650°	700°	750°	800°
Tensile strength	18·6	16·7	15·0	19·5	22·5	21·0	18·6
Elongation per cent.	20·0	9·0	7·0	27·0	45·0	40·0	34·0

and for specimens annealed at 700° for different periods of time :

Time (mins.).	—	5	10	20	30	60	100
Tensile strength	16·5	19·6	20·4	21·4	23·1	21·2	20·5
Elongation per cent.	15·0	23·0	35·0	40·0	48·5	39·5	37·0

J. Arnott, J. Czochralsky, F. Johnson, and R. T. Rolfe discussed the effect of impurities; J. S. Brown, the effect of the time factor; and W. E. Alkins and W. Cartwright, the effect of cold-drawing on the mechanical properties of gunmetal. H. Pealing found no bifilar effect for small oscillations with phosphorbronze strips, but when first used varying values were obtained for the **rigidity** according to the load. The restoring couple per unit angle increased for some days. After annealing, the rigidity becomes constant for varying loads. The anomaly is due to overstrain. A. Weiller, and X. Müller studied the effect of deoxidizers on the alloys. The effect of small proportions of lead, iron, and zinc was examined by F. W. Dick, J. Dewrance, J. Arnott, R. H. Thurston, etc. The **elastic modulus** of an alloy with 88 per cent. of copper was given by W. Voigt as 10,000, and W. Pscheidl as 9194 kgrms. per sq. mm. H. E. Tresca, G. F. Comstock, and F. C. Lea examined the elastic constants of some bronzes. W. Voigt gave 4060 kgrms. per sq. mm. for the rigidity of a 12 per cent. tin bronze; and T. Matsuba studied the **impact test** of bronzes.

H. le Chatelier found the coeff. of **thermal expansion** of an alloy with 10 per cent. of tin to be 0·0000220 at 900°; of one with 20 per cent. of tin, 0·0000270 at 800°; and of one with 30 per cent. of tin at 700°, 0·0000295. P. Braesco gave 0·0$_4$60 for bronzes with 14–29 per cent. of tin between 100° and 300°. P. Hidnert found the coeff. of expansion of cold-rolled alloys to be less than that of cast alloys. F. C. Calvert and co-workers also measured the thermal expansion of these alloys. The curve for the **thermal conductivity** of the bronzes, Fig. 37, was shown by R. Ledoux to be very similar to that for the electrical conductivity. Observations were also made by F. C. Calvert and R. Johnson. C. Künzel found the heat conductivity of an alloy with 4 per cent. of tin was 960 when that of copper was 1000. The **melting point** was shown by R. Mallet, and A. Riche to fall with increasing proportions of tin. The observations of C. T. Heycock and F. H. Neville

FIG. 37.—The Thermal Conductivity of Bronzes.

have been previously indicated. M. Beuling found that lead, and phosphorus made the alloys more fusible, but not so with manganese. According to H. W. Gillet and A. B. Norton, the m.p. of some commercial bronzes, with Cu : Zn : Sn : Pb in the following percentage proportions, are gun-metal (88 : 2 : 10 : 0), 995°; leaded gun-metal (85·4 : 1·9 : 9·7 : 3·0), 980°; red-brass (85 : 5 : 5 : 5), 970°; low-grade red brass (81·5 : 10·4 : 3·1 : 5·0), 980°; bronze with lead (80 : 0 : 10 : 10), 945°; bronze with zinc (84·6 : 5 : 10·4 : 0), 980°; half yellow, half red (75 : 20 : 2 : 3), 920°; naval brass (61·7 : 36·5 : 1·4 : 0), 855°; and manganese bronze, 870°. They also gave for the m.p. of the alloy Cu : Sn in parts by weight, 95 : 5, 1050°; 90 : 10, 1005°; 85 : 15, 960°; and 80 : 20, 890°. C. Künzel found that copper with 10 per cent. of tin and 1 per cent. of phosphorus melted at 1250°; with 9·97 per cent. of tin and 1·17 per cent. of phosphorus, 1242°; and with 10 per cent. of tin and 1·08 per cent. of phosphorus, 1233°. H. Moissan and J. P. O'Farrelly said that an alloy corresponding with CuSn does not change in composition if boiled in the electric furnace, and it is produced when alloys richer in either component are boiled. M. Kühnel, and O. Bauer and H. Arndt investigated the liquation of these alloys; and P. Weise, the electrolytic separation of the copper and tin. W. Biltz found that copper tritastannide has a **heat of formation,** 8 Cals.; a heat of oxidation, 23 Cals.; and that it suffers a 20 per cent. **dissociation** at 1000°.

W. Guertler[10] found that the **electrical conductivity** of copper-tin alloys with the proportion of copper gradually increasing up to that required for CuSn fell from 8·6×10^{-4} to 7·3×10^{-4} mho; the conductivity then remained nearly constant to Cu$_3$Sn when there was a sudden rise to 9·2×10^{-4} mho followed by an abrupt fall to 2×10^{-4} mho; there was then a slow rise to 6·6×10^{-4} with alloys containing 9·7 per cent. of copper, and subsequently a rise up to that of pure copper.
R. Ledoux's results are shown in Fig. 38. R. Ledoux found singular points on the conductivity curve corresponding with Cu_4Sn, and Cu_3Sn, but not with CuSn. E. Bornemann and K. Wagenmann found evidence of Cu_3Sn in their observations on the electrical conductivity of liquid alloys. Measurements were also made by W. C. Roberts-Austen, G. Kamensky, A. Matthiessen and co-workers, R. Edler, W. Harris, O. J. Lodge, E. J. Ball, and R. Ihle. A. Matthiessen and C. Vogt found the conductivity of hard-drawn wires with 1·41 per cent. of tin to be $62·463-0·16713\theta+0·00031363\theta^2$; with 6·02 per cent. of tin, $19·71-0·019626\theta+0·013900\theta^2$;
FIG. 38.—The Electrical Conductivity of Bronzes.

with 11·61 per cent. of tin, $12·102-0·0083587\theta$ $+0·0_53674\theta^2$; with 12·35 per cent. of tin, 10·154 $-0·0067656\theta+0·0_41203\theta^2$; with 14·91 per cent. of tin, $8·8223-0·0048226\theta+0·0_52593\theta^2$; and with 83·60 per cent., $12·764-0·042570\theta$ $+0·0_48734\theta^2$. H. le Chatelier found the **electrical resistance** of an alloy with 10 per cent. of tin to be $0·150+0·0_31900\theta$ ohms. J. Obata studied the effect of a magnetic field on the resistivity of phosphor-bronze. J. Dewar and J. A. Fleming gave for the sp. resistance of commercial phosphor-bronze :

	100°	18·75°	0·8°	−80°	−100°	−182°
Sp. resistance	9071	8581	8483	8054	7883	7371

in electromagnetic units. L. Guillet and M. Ballay examined the influence of cold-work on the electrical resistance. The so-called *bronze silicieux* used for high conductivity wires was shown by F. Gautier to have no silicon ; but silicon was probably used in its manufacture as a deoxidizing agent. A. Weiller, and E. Debié measured the conductivity of phosphor-bronze. M. Herschkowitsch, C. Hocken and H. A. Taylor, G. Kamensky, A. P. Laurie, H. le Chatelier, and G. Tammann measured the electrode potential of the Cu–Sn alloys. A. G. Warren and F. Murphy found the **thermoelectric force** of phosphor-bronze against bronze to be —0·5–0·16 microvolt per degree. R. Ledoux found on the curve for the thermoelectric power, singular points corresponding with Cu_3Sn and Cu_4Sn, Fig. 39. Observations were made by A. Battelli, S. H. J. Wilson, T. J. Seebeck, and E. Steinmann. N. A. Puschin[11] found that the **electrolytic potentials** in N-H_2SO_4 of copper-tin alloys with up to 65 at. per cent. of copper are nearly the same as that of tin alone ; but with 65–68 at. per cent. of copper, there is an abrupt fall,

FIG. 39.—The Thermoelectric Power of Bronzes.

and with up to 74 at. per cent. of copper, it remains nearly the same as that of Cu_2Sn ; with 74–77 at. per cent. of copper, there is a sharp rise very nearly to that required for pure copper. Expressing the proportion of the one element as at. percentages, and the potential, E, in millivolts :

Cu	10	30	40	50	57	60	65	68	73	77	100
E	−4	−2	−4	+4	−3	+4	−3	46	39	480	495

According to M. Herschkowitsch, the potentials of tin towards the copper-tin alloys in a sat. soln. of stannous chloride are :

Sn	11·8	18·6	20·7	25·43	28·19	30·3	34·5	49·7	68·1	80·9
E	188	184	190	195	125	18	5·5	0·6	0·4	0·3

Observations were made by H. E. Armstrong, F. Haber, O. Sackur and H. Pick, P. Lebeau, and A. P. Laurie. G. Tammann and W. Wiederholt studied the cathodic polarization of copper-tin alloys ; and R. Kremann and R. G. Rehenburg

their electrolysis.   O. C. Clifford measured the **magnetic susceptibility** of copper mixed with different proportions of tin, and found :

Sn .	0	1·0	7·0	13·8	24·2	33·2	66·4	97·9	100 per cent.
$k \times 10^{-6}$.	−1·22	−1·13	−1·40	−1·88	−2·07	−2·06	−1·43	+0·28	+0·31

The results are plotted in Fig. 40.   The absence of singularities on the curve may be due to the points near the compound Cu_3Sn being too far apart.

G. Tammann [12] studied the chemical activity of the copper-tin alloys.   E. S. Shepherd and G. B. Upton found that molten bronze absorbs gases which produce blebs as they are evolved on cooling ; bronzes with over 84 per cent. of copper show the effect more than bronzes with a lower proportion of copper.   G. Guillemin and B. Delachanal found that phosphor-bronze retains very little occluded gas, and this consists chiefly of carbon dioxide and hydrogen.   The presence of phosphorus seems to diminish the solubility of hydrogen in bronzes as it also does in the case of iron and steel.   J. Pintsch found bronze does not resist very well corrosion by the gases from gas-engines.   J. B. A. Dumas stated that the tin in

FIG. 40.—Magnetic Susceptibility of Bronzes.

the molten alloy is oxidized by **air** faster than the copper ; E. S. Shepherd and G. B. Upton showed that alloys with over 84 per cent. of copper oxidize most readily, and C. T. Heycock and F. H. Neville found that the higher the proportion of copper in the alloy the faster is it oxidized by air at ordinary temp. or when heated.   E. Heyn and O. Bauer said that cuprous oxide is first formed during the oxidation of the alloy, and that this is immediately reduced by the tin so that the oxygen is always present as stannic oxide which appears as an impurity between the crystals.   The stannic oxide remains as anode-mud when the alloy is made the anode in sulphuric acid.   Phosphorus is a deoxidizing agent ; and A. Philip, and F. von Friese noticed that phosphor-bronzes resist the action of air better than ordinary bronzes.   C. and A. Tissier said that the presence of 1 per cent. of aluminium prevents the oxidation.   This subject was examined by O. Bauer, C. Ratner, B. Setlik, and H. Goldschmidt.   E. Jordis and W. Rosenhaupt said that at 145°, an alloy with 30 per cent. of tin is attacked by dry **oxygen** more rapidly than by the moist gas ; and at 280°, the reverse is true.   S. L. Kneass said that **water-vapour** acts mechanically on the surface of bronze, and that the resistance to attack is conditioned by homogeneity, and sp. gr.

H. von Fellenberg classed ancient bronze objects according to the material in which they have been found : (i) Bronzes from peat-mud are covered by a black earthy mass easily removed ; and the bronze has been preserved owing to the exclusion of the oxygen of the air by the mud of organic origin.   (ii) Bronzes found in water in the beds of lakes and rivers are usually fairly well preserved and are covered with a thin calcareous deposit.   (iii) Bronzes found in the earth—e.g. in graves—have a fine green crust of dark or light verdigris which sometimes has a vitreous lustre.   This crust is known as *patina*—also called *patina antiqua, œrugo nobilis*, and *verde antico*.   Patina varies from a thin film to one several mm. thick. B. G. Sage, and H. Davy noted that below the green crust is a reddish layer of cuprous oxide which comes between the external crust and the bronze itself.   This encrustation is characteristic of bronze which has been slowly changed in moist earth.   According to F. Wibel, there are several kinds of patina : Malachite, $CuCO_3.Cu(OH)_2$; copper oxychloride or atacamite, $CuCl_2.3Cu(OH)_2$; and azurite, $2CuCO_3.Cu(OH)_2$, admixed with silver, stannic oxide, iron oxide, and cupric and lead chlorides.   F. A. Reuss found patinized bronzes with the malachite in direct contact with the bronze, or separated from that metal by a black or bluish layer of cupric oxide.   F. Wibel does not believe that the layer of crystallized cuprous oxide—not always present—represents the first stage in the oxidation of the copper,

while the carbonates represent the later completed stage, as supposed by R. Weber, etc. L. A. Bucholz showed that a strip of copper partly immersed in water and partly in a conc. neutral soln. of copper nitrate, becomes coated with copper and cuprous oxide ; hence, argued F. Wibel, the layer of crystalline cuprous oxide is a reduction product of copper carbonate by the copper of the bronze. He thus described the formation of the patina :

Bronze objects are attacked by waters which contain oxygen, carbon dioxide, and a greater or less percentage of salts. Such soluble salts as are formed are removed by soln., while the bronzes become covered, according to circumstances, with an insoluble layer either of carbonate or of oxide, whereby the form of the objects is preserved. The water then penetrates by capillary action through the porous coating into the interior, and attacks further portions of the metal, forming a layer of soluble cupric salt ; a portion of which is able to pass by diffusion through the external layer. For the same reasons the liquid, bounded as it is on one side by the metal and on the other by the almost insoluble crust, shows varying degrees of conc. : thus, all the conditions necessary for reduction are fulfilled. If the water is rich in salts, a conc. copper soln. is formed and even metallic copper may be deposited from it furnishing the copper crystals of some bronzes ; but if, as is usually the case, the water contains only small quantities of salt, cuprous oxide crystals only are formed. The fact that the process takes place chiefly in the pores made by the water itself is readily understood, because of the comparative quiescence of the liquid ; and that it causes a marked progressive change in the object arises from the continual exchange of a portion of the copper soln. already formed with fresh solvent from outside. Where the absence of carbon dioxide, or other circumstances, hinders the formation of an almost insoluble crust, the reactions detailed above may, under favourable conditions, take place directly upon the surface of the bronze ; if, on the other hand, there is a too rapid change of liquid (as, for example, in very wet localities), the process may altogether fail to set in, since the necessary conditions of rest are wanting. Since the absence of the necessary conditions may arise from a number of purely accidental causes, it will be easily understood that bronzes from one and the same grave may show the same per-centage of carbonates, but very dissimilar percentages of cuprous oxide. In short, all actually observed conditions in which bronzes are found are accounted for by the explanations given above.

E. von Bibra has emphasized the variability of the conditions which determine the formation of patina on bronzes. For example, the effect is dependent on (i) the composition of the alloy ; (ii) the physical character of the alloy—good or bad mixing, fine or coarse grain, etc. ; (iii) the locality in which the alloy has lain ; and (iv) the length of time during which the alloy has been exposed to particular conditions. The effects of organic matter, and of bacteria were emphasized by L. Mond and G. Cuboni. Analyses of bronzes and of the accompanying patinas have been made by A. Terreil, T. Matsuno, J. Schuler, K. Natterer, H. Bassett, A. Arche and C. Hassack, O. Olshausen, and others cited below. The Sn : Cu ratio is often higher in the patina than in the underlying bronze. One of the causes, said J. Schuler, lies in the fact that basic copper carbonate is soluble in water holding carbon dioxide in soln., while stannic hydroxide is insoluble ; and another cause may be found in the action of water containing in soln. ammonia or ammonium carbonate derived from the decomposition of organic matter. In confirmation, several analyses indicate the presence of small quantities of ammonia in patina. E. Friedel noted a peculiar smell associated with a malignant patina. In the extreme case, O. Olshausen, A. H. Layard, H. von Fellenberg, C. Bischoff, A. Philip, and O. Kröhnke found an object originally bronze is represented only by insoluble stannic oxide, all the copper compounds have been leached away. According to F. Rathgen, the blue or green patinas containing oxides and carbonates are more or less stable, and such patinas have been called *Edelpatina*, or *noble patinas;* they are not necessarily prejudicial to the preservation of bronzes. They show a crystalline structure. Carbonate patinas were analyzed by A. Arche and C. Hassack, C. Mitzopulos, J. Schuler, F. Stolba, etc. In addition, some patinas contain chlorides—*vide* **3.** 21, 6—and these, as a rule, are malignant, being the source of one of the *métaux malades*—the *rogna* or *caries* of bronze—which gradually destroys the bronzes—statues, coins, vases, etc.—in museums, the rapidity with which the destruction proceeds being dependent on a number of unknown conditions. Not all

malignant patinas are chloriferous. The presence of chlorides in patina was recognized by W. Haidinger, M. E. Chevreul, A. Terreil, J. Elster, H. Schliemann, and E. Krause. M. Berthelot's observations on this subject will be found 3.21,6; J. Elster regarded the presence of chlorides in the patina of ancient bronzes as a proof that the patina was manufactured intentionally, but F. de Villenoisy showed that it is produced by natural causes and not by the art and methods of the ancient workers in metal. Another series of patinas contains sulphides and sulphates, which were reported by E. Priwoznik, E. Chuard, V. A. Skinder, C. A. de Gouvenain, R. Weber, A. Daubrée, etc. According to F. Rathgen, the presence of sulphides and sulphates does not make a patina malignant. The brown and black colours of patinas described by F. de Villenoisy, F. Rathgen, and J. J. Rein are probably produced by plumbiferous bronzes and sulphides. The production of artificial patina on bronze is described by L. Vanino and E. Scitter, J. Elster, etc., and the cleaning of patina, etc., from bronzes, by F. Rathgen, J. W. Brühl, E. Buchner, etc.

According to L. Révillon and P. Beauverie,[13] **hydrogen dioxide** in alkaline soln. rapidly colours the α-constituent of phosphor-bronze red, blue, and violet; and the phosphide constituent is coloured brown. The bronzes are much less readily attacked by **sea-water** and other corrosive agents than are the brasses or **copper**. If the bronze contains a large proportion of tin, the alloy behaves very much like brass. M. Ledy [14] showed that bronze containing only traces of lead, iron, and zinc is scarcely affected by sea-water because a vessel which had lain at the bottom of the sea for 300 years was only superficially changed. C. Diegel, W. P. Jorissen, and W. A. Tilden confirmed the slowness of the attack by sea-water. A. Philip, and F. von Friese noted that phosphor-bronzes resist the action of sea-water and acids better than ordinary bronzes. The erosion of bronze propeller blades in high-speed steamships varies under apparently identical conditions. The primary cause is usually attributed to the filing action of the water when the propeller is travelling at high velocities, but the fact that the maximum erosive action seldom occurs at the tip of the blades where the helical velocity is greatest, shows that other causes enter largely into the action. O. Silberrad showed that dirt in the casting has little to do with the action; and since there is no increase in the conc. of the copper in the eroded areas, there is not likely to be galvanic action. R. J. Anderson and G. M. Enos, and W. A. Selvig and G. M. Enos studied the corrosion of the bronzes and brasses by acid mine-waters; and the former showed that the grain-size of the metal, between 0·01 and 0·10 mm., does not affect the corrodibility of the metal, although the coarser-grained metal corrodes more readily than when the grain is finer. Some Swedish guns with the inscriptions 1535 and 1622 were recently salvaged from the sea, and the bronze had suffered very little action although it had been submerged nearly 300 years.

M. Herschkowitsch [15] found that **bromine** water readily attacks bronze. D. Mushet found that a small proportion of tin diminishes the attack of copper by **hydrochloric acid ;** and, said L. J. Chaudet, the boiling acid acts preferentially on the contained tin. F. C. Calvert and R. Johnson showed that hydrochloric acid of sp. gr. 1·1, attacks bronze with a small proportion of copper more strongly than tin. H. Behrens made some observations on the action of this acid; and C. T. Heycock and F. H. Neville found that alloys with at least 50 at. per cent. of tin resist best the action of hydrochloric acid mixed with ferric choride; and an alloy corresponding with 80 at. per cent. of copper best resists hydrochloric acid alone. W. A. Tilden found that 7 per cent. hydrochloric acid at 13°–15° dissolved 0·172 grm. per sq. cm. in 14 days, and 0·229 grm. per sq. cm. in 21 days from bronze with 93·31 per cent. copper. The ratio of copper to zinc and tin in the original metal was 100 : 7, and in the dissolved portion 100 : 35. J. G. A. Rhodin measured the rates of evolution of hydrogen when the metals indicated are acted on by 10N-HCl. He assumed that the rate of dissolution is directly proportional to the heats of formation of the ultimate compounds, and to the electrical conductivity of the dissolving metal. He also stated that the barometric press. considerably affects the rate

of dissolution. H. E. Armstrong studied the action of acids on the tin-copper alloys. A. Ledebur found that bronzes usually contain some **sulphur** as well as oxygen, and when heated with hydrogen give off hydrogen sulphide. F. C. Calvert and R. Johnson said that **sulphuric acid** attacks bronze much less vigorously than either of its components. E. Harbeck said that sulphuric acid of sp. gr. 1·53 has virtually no action on bronze even if that alloy be made the anode of a cell. W. A. Tilden found that with sulphuric acid, $H_2SO_4.2H_2O$, no action was observed at 150°, but at 185°–190° in $1\frac{1}{2}$ hrs., 0·115 grm. per sq. cm. was lost by the bronze indicated in connection with hydrochloric acid.

According to H. Behrens, a conc. soln. of **ammonia** dissolves copper from bronze containing 1–12 per cent. of tin, and it is almost without action on bronze with
FIG. 41.—Rates of Dissolution of Metals and Alloys in Hot Hydrochloric Acid.

25 per cent. of tin, and C. T. Heycock and F. H. Neville obtained a similar result with an alloy with 20 at. per cent. of tin. F. C. Calvert and R. Johnson showed that **nitric acid** of sp. gr. 1·25 acts on bronze less vigorously than on copper; and H. Behrens found that the conc. acid attacks alloys with 1–12 per cent. of tin; and alloys with 15–25 per cent. of tin, less rapidly. Electro-deposited bronzes were found by B. E. Curry, and F. Förster, to be attacked with difficulty by this acid. A. Matthiessen also made observations on the action of this acid. W. A. Tilden found that with the bronze previously employed, nitric acid of sp. gr. 1·42 mixed with 15 vols. of water dissolved 0·034 grm. per sq. cm. in 23 days, and the ratio of copper to tin and zinc in the dissolved portion was 10 : 12. B. Feuer studied the corrosion of bronze by aq. soln. of **potassium nitrate.**

H. Behrens found that alloys with 40–90 per cent. of tin are readily attacked by soln. of **potassium hydroxide.** B. Neumann found that during the electrolysis of a soln. of **alkali sulphide** at 70°, with a cupriferous tin anode, the tin was separated from the copper. B. E. Curry determined the rates of corrosion of bronzes of different composition in aq. soln. of different salts, when the bronze was made the anode and a platinum wire the cathode; the proportion of copper in the bronzes varied from 95 per cent. to 5 per cent., with 5 per cent. intervals. Usually a 7 per cent. soln. of the salt was employed, the following soln. being used : sodium
FIG. 42.—Electrolytic Corrosion of Bronzes by Aqueous Solutions of Sodium Sulphate and Chloride.

sulphate, sodium nitrate, sodium acetate, sodium carbonate, alkaline sodium tartrate, ammonium oxalate containing oxalic acid, sodium chloride, sodium persulphate, ammonium sulphate, and copper sulphate. The results with sodium chloride and sulphate are illustrated by Fig. 42. The α-bronzes corrode more rapidly than any others, almost pure copper dissolving; from the $\alpha+\delta$- and $\alpha+\beta$-alloys, copper dissolves more rapidly than tin. The β, δ, $\beta+\gamma$, $\delta+\eta$, $\eta+\epsilon$, and ϵ-bronzes undergo very little change and tend to become passive. The $\epsilon+\zeta$-bronzes become rich in copper on the surface, and tend to disintegrate as the tin dissolves. The cause of certain of the bronzes becoming passive appears to be the formation of a film of stannic oxide. The ϵ-bronze is most resistant to corrosion. No bronze becomes passive in soln. of chlorides, a high current efficiency being observed whatever be the composition of the bronze. In all other salts the curve of current efficiency shows well-marked fields, an abrupt change in the rate of corrosion occurring at the appearance or disappearance of a phase in the equilibrium diagram. The effects of chemical corrosion were in most cases found to be similar in nature to those of electrolytic corrosion.

F. Giolitti and O. Ceccarelli also emphasized the effect of the structure of the bronze on its corrodibility. Under similar conditions, the simultaneous presence in a bronze of the α- and β-solid soln., and especially of the product of segregation of these, accelerates the corrosive action. With bronzes containing not much more than 7 per cent. of tin, the velocity of corrosion increases with the proportion of the β-soln. present, no matter whether such increased proportion is due to a different composition of the alloy or to different thermal treatment, such as altered velocities of solidification and of subsequent cooling. When the proportions of α- and β-solns., and of their segregation products, remain constant, the velocity of corrosion is greater when the differences of conc. of the nuclei and margins of the separate mixed crystals of the two series are greater. As such differences of conc. are observable under the microscope, the degree of resistance of a bronze to corrosion may be determined beforehand by the same means. According to O. Sackur and H. Pick, copper-tin alloys containing 0–56 per cent. of copper precipitate lead from a soln. of lead chloride up to the same equilibrium point as does tin itself, so that they contain free tin. Alloys containing 57–60 per cent. of copper do not precipitate lead from lead chloride soln., or copper from cuprous iodide soln., but cause the separation of copper from soln. of cuprous chloride and bromide. Alloys containing more than 60 per cent. of copper do not precipitate copper from the two soln. last mentioned, but do so from soln. of the chloride and sulphate.

L. Guillet [16] found that an ammoniacal soln. of cuprous chloride is a good etching fluid for these alloys. A. Gawalowsky observed that brewers' mash does not attack bronze, and he examined the action of raw petroleum, mineral lubricating oil, rape oil, and ice-cream on the metal.

A. Weiller [17] examined the effect of *sodium* on copper-tin alloys; and A. Detlik [18] and co-workers, C. Bürgel, and M. Reiche, the effect of *calcium*. The effect of *zinc* in forming zinc-bronzes, and tin-brasses has been discussed by H. Behrens,[19] J. B. A. Dumas, etc. The ternary alloys with over 60 per cent. of copper were examined by G. Tammann and M. Hansen. The m.p. curve is given in Fig. 43. It was found that the constituents of alloys containing less than 35 per cent. Zn resemble those of the binary copper-tin alloys, α-, β-, and-γ series of ternary mixed crystals being formed. The solubility of tin in α mixed crystals decreases with increasing zinc content. Copper-rich alloys, on cooling from the melt, deposit first α ternary mixed crystals. If sufficient tin and zinc are present, these undergo a peritectic reaction corresponding to the change α+liquid→β; this change occurs at about 800° in the binary copper-tin alloys, and the temp. is little affected by small quantities of zinc, but is raised by larger quantities. Alloys containing less copper, on cooling from the melt, deposit first β crystals which may undergo a peritectic reaction corresponding to the change β+liquid→γ. The β and γ ternary mixed crystals both undergo eutectoid transformations in the solid state, corresponding to the changes β→α+γ, and γ→α+δ.

FIG. 43.—Melting-point Curves of Cu–Zn–Sn Alloys with over 60 per cent. of Copper.

The former change occurs at about 580°, and its temp. is little affected by increasing zinc content. The latter is little affected by increasing zinc content. The latter change occurs at about 520° in the binary copper-tin alloys, and its temp. is raised by the addition of zinc until, if sufficient zinc is present, the two reactions proceed simultaneously, β+γ→α+δ. The δ-phase consists of the compound Cu_4Sn and does not form mixed crystals. Alloys containing more than 35 per cent. Zn, and only small amounts of tin, give rise to ternary β and β' constituents resembling those of the copper-zinc binary alloys, but the range of the ternary alloys having constituents which resemble those of the copper-tin system is much the larger. The structure of the technically important alloys depends greatly on the conditions of cooling and heat treatment. The effect of *cadmium* was examined by G. Chandoir, and M. Gruber.

E. S. Sperry,[20] C. and A. Tissier, H. Grossmann and F. Krupp, T. Matsuda, M. H. Lançon, and Chemische Fabrik vorm. E. Schering examined the effect of *aluminium*; T. Slater,[21] the effect of *chromium*; M. Beuling,[22] E. W. L. Biermann, A. H. and E. H. Cowles, C. Künzel, H. Behrens, M. Lévitzky, A. Ledebur, E. S. Sperry, and P. M. Parsons, the effect of

manganese. H. S. Primrose, L. C. Glaser and H. J. Seemann, and M. Levi-Malvano and F. S. Orofino [23] studied alloys of tin, copper, and *phosphorus.* They found the f.p. of the binary system Cu_3P–Cu_3Sn to be:

Cu_3P	.	.	68·65	60·00	40·00	20·00	10·00	5·00	1·00 per cent.
F.p.	.	.	870°	830°	740°	650°	690°	700°	710°

with the eutectic at 650°, and 22 per cent. Cu_3P. They also studied the ternary system Cu–Cu_3P–Cu_3Sn. The alloys of tin and copper with *antimony* have been investigated by C. Karmarsch,[24] G. Charpy, W. Schulte, etc. ; they are used as *anti-friction or bearing metals,* because they do not heat so rapidly by the revolving metal it supports. The bearing metals are represented by *babbit metal*—88·88 per cent. Sn ; 7·4 per cent. Sb ; and 3·7 per cent. copper. Antimony is used in *die-casting alloys* to lessen the shrinkage. These alloys are of three types according as zinc, lead, or tin are the basal metals. Those with a zinc base vary from 73 to 92 per cent. of zinc, up to 31 per cent. of tin, 1 to 20 per cent. of copper; up to 10 per cent. of antimony; up to 6 per cent. of aluminium; and up to 10 per cent. of lead. T. J. Johnston gives the following list of alloys of antimony. Taking the percentage amounts of lead, antimony, and tin in order, *electrotype,* 94, 4, 3 ; antimonial lead, 80 to 87, 13 to 20, — ; *jacoby metal,* 85, 10, 5 ; *linotype,* 83, 12, 5 ; *magnolia,* 80, 15, 5 ; standard *sohite-metal,* 71, 24, 5 ; *graphite metal,* 68, 17, 15 ; and standard *type-metal,* 58, 26, 15 with ore per cent. of copper. The alloys of tin and copper with *bismuth* were studied by C. Bischoff,[25] J. Novel, etc. ; and those with *vanadium,* by N. A. Helouis.[26] The tin-copper alloys with *lead* have been examined by A. Erdmann,[27] A. Salvétat, M. Donovan, etc. ; with *iron,* by O. Skinder,[28] C. Bischoff, R. Hunt, E. Edmonds, and E. J. Maumené ; with *nickel,* by C. Bischoff,[29] L. Elsner, etc. ; and with *cobalt,* R. Wagner [30] made a violet bronze. Bronze coins of the Sung Dynasty in China contained 20–25 per cent. of lead.[31]

§ 8. Alloys of Tin with Silver and Gold

A. F. Gehlen [1] observed that silver and tin readily combine without incandescence, and the sp. gr. of the product exceeds the mean between the sp. gr. of the constituents. An alloy with silver and tin in the proportion 2 : 1 is hard, and one with the proportion 1 : 2 is malleable. The molten elements, said C. R. A. Wright, are mutually soluble in all proportions. H. Weiss studied the neutral diffusion of silver and tin. F. Mylius and O. Fromm obtained an alloy with a variable composition, by adding tin to a dil. soln. of silver sulphate. The thermal diagram was studied by C. T. Heycock and F. H. Neville, H. Gautier, and G. Charpy. R. A. Joyner, like G. I. Petrenko, found that if well annealed, the silver-tin alloys show the presence of one compound, Ag_3Sn ; and with alloys containing over 50 per cent. of tin, a solid soln. of silver in silver tritastannide ; the latter compound becomes stable below 490°. If the cooling be rapid, the solid soln. may be retained in the solid castings. The fusion curves obtained by G. I. Petrenko are shown in Fig. 44. The eutectic is at 220° with a mixture containing 3·5 per cent. of silver. The sat. solid soln. with 25 per cent. of tin decomposes on cooling, forming **silver tritastannide,** Ag_3Sn, and a solid soln. with 19 per cent. of tin. The tritastannide is dimorphous α-$Ag_3Sn \rightleftharpoons \beta$-$Ag_3Sn$ with a transition temp. 232°, nearly. A. J. Murphy could not confirm this transition point ; but by electrical measurements he found a transformation occurs at 60°. He also found that the solid soln. of tin in silver contains a maximum of 13·3 per cent. tin at 724°, and this slowly falls to just below 11 per cent. at 100°. This α-soln. reacts with liquid at 724° to

form a second solid soln., β, which is the sole constituent of alloys containing 12·5–19 per cent. tin at 20°, and of alloys containing 13–24 per cent. tin at 480°; at 724°, it contains 14·5 per cent. tin. The $\alpha+\beta$ field is a narrow belt extending over the range 13·3–14·5 per cent. tin at 724° and 11–13 per cent. tin at 20°. The γ-constituent is the compound Ag_3Sn, which exists in a narrow range of less than one per cent. in the vicinity of 26 per cent. Sn., the $\beta+\gamma$ field occupying the space between the β and γ ranges mentioned above. Alloys containing more than 27 per cent. Sn. are all composed of γ and tin containing less than 0·1 per cent. silver in solid soln. The α-solid soln. is characterized by prolific twinning accompanied by the development of finer marking following the course of cleavage planes in the crystals. The β-solid soln. consists entirely of polygonal crystals without any surface markings, and the compound Ag_3Sn, after prolonged annealing, of polygonal crystals with fine cross-hatch markings. The addition of even very small quantities of silver to tin suppresses both the allotropic transformations, 0·1 per cent. silver preventing the tin from changing to the grey variety even after three weeks at −78°. The sp. gr. of the aged filings of the tritastannide is 9·83; the X-radiogram correspond with a close-packed hexagonal lattice of side $2·98 \times 10^{-8}$ cm., and axial ratio $a : c = 1 : 1·61$; and the mean coeff. of linear expansion is 0·0000222 between 16° and 236°. Measurements of the electrical resistance were also made. D. H. Andrews and J. Johnston studied the solubility of silver in tin.
FIG. 44.—The Fusion Curves of the Sn–Ag Alloys.

W. Vaubel said that *silver tetritastannide* is produced by the action of tin hydride on soln. of silver nitrate. The microstructure of the alloys was examined by G. I. Petrenko, A. J. Murphy, C. T. Heycock and F. H. Neville, G. Charpy, R. A. Joyner, W. Campbell, and K. Endell and H. Hanemann. A. Westgren and G. Phragmen studied the X-radiograms of these alloys; and F. Schmidt, the surface-tension of tin-amalgams. A. Matthiessen gave for the sp. gr. :

	14·8°	12·9°	13·9°	16·3°	19·3°	18·4°	18·8°	18·6°
Ag : Sn	4 : 1	2 : 1	1 : 1	1 : 2	1 : 3	1 : 6	1 : 9	1 : 18
Sp. gr.	9·953	9·507	8·823	8·223	7·963	7·666	7·551	7·421

E. von Maey found the sp. vol. curve had a singular point corresponding with the tritastannide. H. Behrens said that there are maxima in the hardness curve corresponding with Ag_4Sn and Ag_2Sn. H. Gautier, and G. Charpy also made observations on the hardness of these alloys. W. C. Roberts-Austen measured the diffusion of silver in tin; and F. Saeftel and G. Sachs, and G. Wertheim, the elastic properties. J. J. van Laar, W. C. Roberts-Austen, and A. W. Smith discussed the m.p. curves. J. Marttinen and J. R. Tiihonen studied the sp. ht. and the latent heat of tin amalgams; A. W. Smith, the thermal conductivity; and A. L. Bernoulli, the optical properties. The relation between the thermal and electrical conductivities was studied by A. L. Bernoulli, C. Hardenbeck, and R. Schenck. Some of A. Matthiessen and co-workers' observations on the electrical conductivity are indicated in Fig. 45. The thermoelectric force of an alloy with 4 per cent. of tin against copper was 7·6 microvolts at 18°, and 5·5 at 80°. M. Herschkowitsch found that the curve showing the electrolytic potentials of these alloys has a singular point corresponding with Ag_4Sn. N. A. Puschin showed that the e.m.f. of the cell $Sn \mid N\text{-}H_2SO_4 \mid SnAg_n$ corresponded with the existence of Ag_5Sn or Ag_6Sn. M. Herschkowitsch measured the electrode potentials of these alloys. T. J. Seeback, and A. Batelli studied their thermoelectric properties. The alloy oxidizes readily; and, added J. J. Berzelius, the tin is best separated by distilling

the alloy in the form of filings with mercuric chloride. According to H. Moissan and T. Watanabe, if an alloy with 36·98 per cent. of silver is heated for 10 mins. in a high temp. electric furnace, the residue retains only 2·93 per cent. silver.

Silver-tin alloys are employed in making *dental-amalgams*, and the binary alloy appears to undergo profound changes through the lapse of time. G. V. Black showed that the fresh filings require for amalgamation half as much mercury again as similar filings which have been kept for some months, or heated for half an hour to 100°. The ageing does not occur in a bar of alloy during several weeks' heating under conditions where the filings are aged in half an hour. Exclusion of air does not affect the results. Amalgams obtained from freshly prepared filings exhibit volume changes different from those made from aged filings. The effect of *the ageing of silver-tin alloys* low in silver is as pronounced as with alloys containing much of that metal. R. A. Joyner found no difference in the solid amalgams from aged and unaged filings. W. A. Knight and J. A. Joyner showed that the ageing is not due to the formation of a film of oxide, to the adsorption of oxygen, or to the acceleration of a polymorphic change due to the introduction of iron during the filing. W. A. Knight also showed that the filings are not aged by ozone, and there is no evidence of the formation of any film of oxide during ageing. He found that in the ageing of silver-tin alloys—during which the filings lose part of their power of combining with mercury—there is no perceptible change in weight, but the vol. diminishes, and with the alloy Ag_3Sn, the change is about 0·4 per cent. In solid soln. containing silver, the ageing is roughly proportional to the amount of silver tritastannide present, vanishing completely for pure tin—*vide infra*, mercury alloys. For H. Péchaux's hypothesis, *vide infra*, aluminium-silver alloys. Alloys of aluminium with tin, bismuth, or magnesium appear to exhibit the phenomenon of ageing, but not those of aluminium with lead or zinc. Observations were also made on this subject by J. W. McBain and co-workers, A. Fenchel, and A. W. Gray. The last-named regarded the ageing as a process analogous to the annealing of brasses, bronzes, etc., for it consists in the recrystallization of amorphous material produced by the severe deformation of silver tritastannide crystals during the comminution of the alloy—**3.** 21, 5. G. T. Beilby has shown that the result of mechanical work on metals may change them from the crystalline to the amorphous state. G. Tammann studied the electrode potential and chemical properties of these alloys.

FIG. 45.—The Electrical Conductivities of the Sn-Ag Alloys.

According to C. Hatchett,[2] small quantities of tin make gold less ductile but do not make it brittle ; gold and tin in the proportion 11 : 1 make a pale yellow, slightly malleable alloy with a fine-grained fracture, and a sp. gr. 17·307, indicating that the vol. is less than the sum of the vols. of the constituents. F. Mylius and O. Fromm prepared an alloy of variable composition by the action of tin on a soln. of auric chloride. C. F. Rammelsberg discussed the crystalline character of the alloy ; and F. M. Raoult, the substitutions of the constituents by other metals in soln. of their salts. R. Vogel found that the curve of fusion, Fig. 46, falls sharply from the m.p. of gold to a eutectic point at 280° and 20 per cent. of tin. It then rises to a well-defined maximum at 418°, corresponding with 37·63 per cent. of tin and representing **gold monostannide,** AuSn, which forms a silver-grey mass more brittle and hard than either gold or tin, and with an electrical conductivity greater than all

FIG. 46.—The Fusion Curves of the Sn–Au Alloys.

the gold-tin alloys excepting those with over 95 per cent. of gold. It is as resistant as gold to the action of sulphuric, nitric, or hydrochloric acid, and is only slowly attacked by aqua regia. The fusion curve, after passing through the maximum at 418°, falls to a second eutectic at 217° and 90 per cent. of tin, finally rising to the m.p. of tin. The curve between the first maximum and the second eutectic has two breaks, one at 308°, and 60 per cent. of tin corresponds with **gold distannide,** $AuSn_2$, which appears as large crystals in the slowly cooled alloy, and it is as resistant towards acids as the monostannide. At 308°, it is transformed $AuSn \rightleftharpoons 0.59AuSn$ + fused alloy ($0.403Au+1.403Sn$). The second break at 252° and 80 per cent. of tin, corresponds with **gold tetrastannide,** $AuSn_4$. This compound is coloured brown by nitric acid while the distannide is not changed. At 252°, it is transformed $Sn+AuSn \rightleftharpoons 0.85AuSn_2+$ fused alloy ($0.15Au+0.15Sn$). C. T. Heycock and F. H. Neville, R. Vogel, H. le Chatelier, W. C. Roberts-Austen, and C. H. Desch made observations on the eutectic mixture, and microstructure. A. Matthiessen found the sp. gr. of a number of gold-tin alloys :

	15·4°	14·2°	14·6°	23·70°	23·7°	23·7°	24·6°	23·1°	22·9°
Au : Sn .	4 : 1	2 : 1	1 : 1	2 : 3	1 : 2	1 : 3	1 : 4	1 : 6	1 : 50
Sp. gr. .	16·37	14·243	11·833	10·794	10·168	9·405	8·931	8·470	7·441

E. von Maey measured the sp. vol. of these alloys ; W. C. Roberts-Austen, the tensile strength, and also the diffusion of gold into tin ; C. T. Heycock and F. H. Neville, and J. A. Mathews, the lowering of the f.p. ; A. Matthiessen, the coeff. of cubical expansion, and the electrical conductivity. There were two minima on the conductivity curve corresponding with Au_4Sn and Au_2Sn_5. N. A. Puschin found no evidence of the tetrastannide in his measurements of the electrolytic potential of these alloys, but he did find singularities in the curve corresponding with SnAu, and Sn_2Au. A. P. Laurie, and H. le Chatelier discussed the e.m.f. of a cell with a gold-tin alloy in a soln. of stannic chloride and gold in a soln. of auric chloride. G. Tammann studied the electrode potential and chemical properties of the gold-tin alloys ; and G. Tammann and W. Wiederholt, the cathodic polarization.

§ 9. Alloys of Tin with the Metals of the Alkaline Earths, and of the Zinc Family

J. L. Gay Lussac and L. J. Thénard [1] failed to make a *tin-barium alloy* by heating a mixture of baryta and charcoal with tin to a white heat; but H. Caron claimed to have obtained such an alloy by heating a mixture of sodium carbonate, barium chloride, carbon, and finely divided tin until sodium vap. was no longer evolved. J. L. Gay Lussac and L. J. Thénard failed to make a *strontium-tin alloy* by heating tin with a mixture of strontia and carbon to whiteness; nor was a *calcium-tin alloy* obtained from a mixture of lime and carbon. H. Moissan said that tin heated to a temp. above its b.p., unites with calcium to form a crystalline alloy which has a sp. gr. 6·70 when 3·82 per cent. of calcium is present. This alloy decomposed cold water very slowly. B. Setlik made a brittle, crystalline alloy by melting the two metals under borax, when much calcium was lost in the operation. C. T. Heycock and F. H. Neville measured the lowering of the f.p. of tin by calcium.
FIG. 47.—The Fusion Curves of the Ca–Sn Alloys.

E. Kordes studied the eutectic mixtures; and M. Chikashige, the colour of the alloys. L. Donsky found that calcium dissolved in tin at about 650°, and he examined alloys with up to 18 per cent. of calcium. The f.p. curve, Fig. 47, rises steeply from the m.p. of tin to a miximum at 623° and 10·1 per cent. of calcium, corresponding with calcium tristannide, $CaSn_3$, and then falls to a eutectic point at 603° and 14·9 per cent. of calcium. According to W. Hume-Rothery, the addition of calcium to tin produces a sharp rise in the f.p., and the liquidus rises to a maximum at 627°, Fig. 47, corresponding with the pure compound $CaSn_3$. From here the liquidus falls slightly to a eutectic point of composition 31·2 at. per cent. calcium and temp. 609°, the eutectic constituents being the compounds $CaSn_3$ and $CaSn$. From this point the liquidus rises to 987°, the m.p. of the compound $CaSn$, which corresponds to a slight break in the liquidus but not to a maximum. The liquidus continues rising to a maximum at 1122° C., corresponding to the compound Ca_2Sn, and falls

abruptly to a eutectic of Ca_2Sn and calcium at 759° C., the eutectic composition being 81·41 at. per cent. calcium, from which point the liquidus rises to the m.p. of calcium. No evidence of the existence of solid soln. has been found. The system Ca–Sn is similar to the system Ca–Pb, except that the three compounds all have slightly higher m.p. than the corresponding lead compounds. The white crystals of **calcium hemistannide,** Ca_2Sn, have a sp. gr. 3·47 at 0°, and melt at 1124°. As with the preceding compound, the hemistannide is immediately attacked by air, water, and dil. hydrochloric acid. The crystals of **calcium stannide,** $CaSn$, cleave into thin plates a little paler in colour than mercury. The sp. gr. is 4·17 at 0°. As in the case of the preceding compound, it is immediately attacked by air, water, and dil. acid—the reaction with water is more violent than with dil. acid. The silver-white **calcium tristannide,** $CaSn_3$, has a sp. gr. 6·01 at 0°, and it melts at 627°; it probably crystallizes in the cubic system. It quickly tarnishes in air, and the calcium, not the tin, is oxidized. The natural faces of the crystals are less rapidly attacked than ground or polished surfaces. The compound is at once attacked by water, forming tin and calcium hydroxide; it gives off hydrogen with hydrochloric acid. W. Biltz and W. Holverscheit gave 43 Cals. for the heat of formation of the tristannide; 45 Cals. for the heat of oxidation; 5·989 for the sp. gr. at 25°; and 66·15 for the mol. vol. when the additive rule gives 74·8. According to L. Donsky, alloys containing up to 4 per cent. of calcium are harder than tin and fairly tough; with a further increase of calcium they become brittle. Those containing 2 per cent. of calcium are acted on by cold water. O. Ruff and H. Hartman studied the absorption of nitrogen by these alloys. C. G. Carroll and W. H. Adams patented an alloy of tin and calcium as a solder for aluminium. They claimed that the calcium reduced the oxide on the surface of the metal to be soldered. R. Kremann and co-workers measured the e.m.f. of calcium against the calcium-tin alloys. K. Jellinek and J. Wolff studied the equilibrium relations in the electrolysis with tin electrodes of fused mixtures : $Ba+2KCl \rightleftharpoons BaCl_2+2K$, and with sodium in place of potassium. C. A. Kraus and H. F. Kurtz observed the formation of *calcium pentitastannide,* Ca_5Sn, in the reduction of tin salts by calcium amalgams.

J. Parkinson [2] melted a mixture of *tin and magnesium* in an atm. of hydrogen, and obtained brittle alloys; he also melted the two metals under a layer of fused sodium chloride and calcium fluoride. E. Beck found that the preparation of the alloys from the oxides under a flux of fluorides was not satisfactory. T. L. Phipson also made alloys of these elements by the fusion process. G. Masing said that if a mixture of the finely divided elements be compressed a small proportion of an alloy is formed. W. Borchers and E. Beck made the alloys electrolytically. G. Grube studied the m.p. curve, Fig. 48. W. Hume-Rothery also studied the f.p. curve; E Kordes, the eutectic. Magnesium does not seem to be soluble in tin, but it dissolves about 6 per cent. of tin. G. Grube found that the curve falls from the m.p. of magnesium to a eutectic point corresponding with the temp. 564·8° and 39 per cent. of tin; it then rises to a maximum point at 783·4° and 70·95 per cent. of tin. From the maximum point, which indicates the existence of **magnesium hemistannide,**

FIG. 48.—The Fusion Curves of the Sn–Mg Alloys.

$SnMg_2$, it falls to a second eutectic point at 209·4° and 97·5 per cent. of tin, and finally rises to the m.p. of tin. $SnMg_2$ is formed with considerable development of heat on melting together its constituents in hydrogen at 700°–800°; it crystallizes well, is brittle, and easily tarnishes in the air. Analogous observations were made by N. S. Kurnakoff and N. J. Stepanoff; they placed the eutectics at 580° and 203·5°; and gave 795° for the m.p. of the hemistannide.

The compound has a well-marked octahedral cleavage which makes the alloys brittle. According to L. Pauling, the X-radiograms of the hemistannide correspond with the calcium fluoride structure, there being eight magnesium atoms round each tin atom at the corners of a cube, and four tin atoms round each magnesium at the corners of a tetrahedron. The constants are d_{100}=6·78 A., and the closest approach of the tin and magnesium atoms in the lattice, 2·94 ± 0·01 A. The sp. gr. of the compound is 3·591 at 20°/4°, and its hardness 3·5. W. Biltz and W. Holverscheit gave 3·625 for the sp. gr. at 25°, and 46·2 for the mol. vol. when the additive rule gives 44·3. According to N. S. Kurnakoff and N. J. Stepanoff, the atomic lowering of the f.p. of tin by magnesium agrees with the calculated value —1. 10, 13. C. T. Heycock and F. H. Neville also measured the lowering of the f.p. of tin by magnesium; and W. Hume-Rothery found the lowering of the f.p. agrees with the formula Mg_4Sn_2. A. von Vegesack gave 565° and 209° for the two eutectics, and 783° for the m.p. of the hemistannide. W. Biltz and W. Holverscheit found the heat of formation of the hemistannide to be 49 Cals., and the heat of oxidation 57 Cals. T. L. Phipson's alloy with 85 per cent. of tin was lavender-blue, and decomposed water at ordinary temp. E. Beck said that the molten alloy containing 50·1 per cent. of tin absorbs 40 per cent. of nitrogen; and W. Borchers and E. Beck recommended it for a process for extracting nitrogen from the air.
FIG. 49.—The Electrical Conductivities of the Sn–Mg Alloys.
FIG. 50.—Fusion Curves of the Binary System: Sn–Zn.

The curve, Fig. 49, by N. J. Stepanoff represents the electrical conductivities of these alloys; he also measured the temp. coeff. of the resistance. C. H. Green studied the eutectic structure of the alloys. The subject was discussed by A. W. Smith, and C. A. Kraus. G. Tammann studied the electrode potential and chemical properties of these alloys. R. Kremann and H. Ruderer found evidence of the formation of $MgSn_2$ in their study of the e.m.f. of these alloys.

F. Rudberg [3] found that the *zinc-tin alloys* are readily formed and that the combination Sn_6Zn has one f.p.; *viz.* 204°, while other alloys have a higher f.p., which varies with the nature of the alloy, and which separates first on cooling. When the excess has crystallized out, the Sn_6Zn combination separates last at, in modern language, the eutectic temp. G. Charpy, R. H. Thurston, and C. T. Heycock and F. H. Neville found that the two metals are mutually soluble in all proportions in the fluid state. B. E. Curry found that, at 180°, a solid soln. with up to 7 per cent. of zinc is formed. C. R. A. Wright assumed that a compound, *zinc tetritastannide*, Zn_4Sn, is formed, but this has not been confirmed. C. T. Heycock and F. H. Neville, W. Guertler, E. Crepaz, R. Lorenz and D. V. Plumbridge; M. Levi-Malvano and O. Ceccarelli, P. T. Arnemann, and L. Losana and E. Carozzi investigated the fusion curve of the tin-zinc alloys. The results are summarized in Fig. 50. The eutectic is at 197°, and 9·7 per cent. of tin. The transformation with 53 per cent. of tin at 348° represents a modification of zinc indicated by L. Losana; another transformation occurs at 161°. F. Rudberg gave 204° for the eutectic temp.; W. Campbell, and D. Mazzotto, between 190° and 195°; G. H. Wiedemann,

197°; and C. T. Heycock and F. H. Neville, 198°. P. G. J. Gueterbock and G. N. Nicklin studied the effect of zinc as an impurity on the physical properties of tin; D. H. Andrews and J. Johnston, the solubility of zinc in tin; and A. M. Portevin, and E. Kordes, the eutectic mixture. G. Vicentini said that the microstructure is difficult to interpret owing to the tendency of the alloy to liquate or segregate. The microstructure was studied by B. E. Curry, C. H. Green, H. Gautier, P. Rosbaud and E. Schmid, and H. Behrens; J. H. Croockewit, G. C. Lowe and co-workers, A. Matthiessen, and T. Thomson measured the sp. gr. of some alloys; and F. C. Calvert and R. Johnson found that with the at. ratio:

Zn : Sn	1 : 2	1 : 1	2 : 1	3 : 1	4 : 1	5 : 1	10 : 1
Sp.gr	7·274	7·262	7·188	7·180	7·155	7·140	7·135

E. von Maey studied the sp. vol. of these alloys; E. Wiedemann, and C. M. Marx, the change in vol. during freezing; L. Guillet, G. Sachs, and C. di Capua, the hardness of these alloys; G. Wertheim, the elastic properties. A. Matthiessen measured the cubical coeff. of thermal expansion of the $Sn_4 : Zn$ alloy and found that at $\theta°$, $v = v_0(1 - 0·0_4236\theta + 0·0_7822\theta^2)$. F. A. Schultze found the thermal conductivity of the alloy, Fig. 51, was in accord with G. Wiedemann and R. Franz's rule. W. B. Brown, and A. W. Smith measured the thermal con-
FIG. 51.—The Thermal Conductivities of the Sn–Zn Alloys.
FIG. 52.—The Electrical Conductivity and Thermoelectric Power of the Sn–Zn Alloys.

ductivity. A. Magnus and M. Mannheimer observed a rise of temp. when molten tin and zinc are mixed. M. Herschkowitsch found for the heats of formation, per gram-atom of zinc, for alloys with 32·73, 62·60, 83·60, and 90·82 per cent. of zinc the respective values 106·9, 106·3, 97·63, and 97·59 Cals. J. Tayler also measured the heats of formation of these alloys. D. Mazzotto found the latent heat of fusion of the $Sn_{20} : Zn$-alloy, 15·091; $Sn_{12} : Zn$, 16·252; $Sn_2 : Zn$, 23·484; and $Sn_7 : Zn$, 16·20 cals. The electrical conductivity was measured by A. Matthiessen and C. Vogt, W. Guertler, W. S. Harris, H. le Chatelier, and G. Vicentini and C. Cattaneo. The results of F. A. Schultze, plotted in Fig. 52, for the vol. percentage of zinc, are:

Zn	100	70·19	53·83	36·95	23·34	12·78	8·93	0
Cond. ×10⁻⁶	16·20	13·28	12·35	11·10	10·09	9·59	9·28	8·57

M. Herschkowitsch measured the electrolytic potential of the alloys against zinc in N-$ZnSO_4$; and A. P. Laurie, P. Fuchs, and N. W. Taylor made observations on this subject. R. Kremann and O. Baukovac studied the electrolysis of these alloys. The thermoelectric force was measured by W. Rollmann, A. Battelli, and E. Rudolfi. The results of the last-named are plotted in Fig. 52. H. E. Armstrong reported some tests on the action of acids on this alloy. C. Montemartini and E. Colonna investigated the action of nitric acid on these alloys, and the formation of ammonia during the reaction. C. Karmarsch, and A. Guettier studied the technical uses of different zinc-tin alloys; J. W. Richards suggested the $Sn_4 : Zn_3$

alloy as a solder for aluminium ; and J. Habermann recommended the alloy with 83 per cent. of zinc for the production of hydrogen from acids. S. D. Muzaffar studied the ternary system Sn–Zn–Bi ; and S. L. Hoyt, H. L. Reason, L. Guillet, O. F. Hudson and R. M. Jones, and G. Tammann and M. Hansen, Cu–Zn–Sn—*vide* Cu–Sn alloys. H. B. Lambert used a tin, zinc, antimony alloy as a solder for aluminium. W. Campbell studied the ternary system Zn–Sn–Sb, and C. R. A. Wright, and W. Campbell, Zn–Sn–Bi.

F. Rudberg,[4] and B. Wood prepared *cadmium-tin alloys*. The equilibrium

FIG. 53.—The Fusion Curves of the Sn–Cd Alloys.

diagram, and the m.p. of the alloys have been examined by A. Stoffel, C. T. Heycock and F. H. Neville, A. W. Kapp, A. P. Schleicher, H. Behrens, D. Mazzotto, R. Lorenz and D. V. Plumbridge, H. le Chatelier, K. Honda and T. Ishigaki, and A. Bucher. According to A. Bucher, tin and cadmium are mutually soluble to the extent of 3 per cent. in the solid state. A. Stoffel's results are indicated in Fig. 53. No definite compound appears to be formed, but the solid alloy has a transition point at 125° which is thought to indicate the possible formation of *cadmium tetrastannide*, CdSn$_4$. H. Behrens, C. H. Green, E. Schrader, and A. Stoffel examined the microstructure of these alloys. A. Matthiessen measured the sp. gr. of the alloys with different atomic proportions :

Sn : Cd				6 : 1	4 : 1	3 : 1	1 : 1	1 : 1	1 : 4	1 : 6
Sp. gr.	.	.	.	7·434	7·489	7·690	7·904	8·139	8·336	8·432

M. Herschkowitsch gave 103·7, 94·82, and 84·29 Cals. for the heat of formation of alloys with respectively 26·35, 56·05, and 92·21 at. per cent. of cadmium. E. Schrader examined the heating curves. L. Schüz found the sp. ht. of an alloy Sn$_2$: Cd to be 0·0560 at 100°, and 0·0554 at −77°. The electrical conductivity was measured by A. Stoffel, A. Bucher, A. Schulze, and A. Matthiessen. The results by the last-named appear as a straight line in Fig. 54. The electrolytic
FIG. 54.—The Electrical Conductivity, and Thermoelectric Power of the Sn–Cd Alloys.
FIG. 55.—Freezing-point Curves of the Ternary System : Sn–Cd–Bi.

potential was measured by A. P. Laurie, H. le Chatelier, P. Fuchs, N. W. Taylor, and M. Herschkowitsch, and the thermoelectric power, by E. Rudolfi, A. Battelli, and A. Bucher. The results by the first-named are indicated in Fig. 54. A. Gawalowsky used the alloy with 60 per cent. of cadmium for colour making. A. Magnus and M. Mannheimer observed that a rise of temp. occurs when molten tin and cadmium are mixed. W. Campbell studied the ternary system Sn–Cd–Sb ; A. Räder, Sn–Cd–Zn ; and W. Spring, and D. H. Andrews and J. Johnston, Sn–Cd–Bi ; A. Stoffel investigated the f.p. of the ternary system Sn–Cd–Bi, and the results are indicated in Fig. 55. The eutectic at 103·7° corresponds with 33·2 per cent. of tin, 27·5 per cent. of cadmium, and 39·3 per cent. of lead.

No compounds are formed. R. Kremann and K. Thomis measured the e.m.f. of those ternary alloys.

Tin and mercury unite quickly even at ordinary temp., and still more rapidly if mercury be poured into molten tin. J. F. Daniell [5] said that

A piece of tin, the lower end of which is immersed for four weeks in mercury, is penetrated through and through by the mercury, and exhibits cracks ; its lower end becomes attenuated by soln. of the metal, and the immersed part is found to be covered with six-sided tables, some of which float about in the mercury. If a square bar of tin, whether cast in a square form, or hammered or filed square from a round bar, be kept for a few days under mercury, it splits in directions proceeding from the lateral edge to the opposite diagonals, thereby dividing itself into four triangular prisms, easily separated by a knife ; at the same time, a four-sided pyramid is formed at each end of the square bar. If the piece of tin has any other form, cracks are produced in other directions.

R. H. Weber made amalgams rich in tin by bringing the metals together under a layer of mercury. J. Schumann poured molten tin into mercury. A. C. Becquerel made them by his electrocapillary process. E. N. Horsford, R. Böttger, and L. Arons also made the amalgams from the constituent elements. J. Nicklès said that tin is attacked by mercury less rapidly than zinc, but more rapidly than lead. A. Gouy measured the solubility of tin in mercury ; and R. A. Joyner gave :

	14°	25·4°	63·2°	90°	163°
Sn	1·05	1·24	4·04	18·0	66·7 at. per cent.

J. Regnauld said that heat is absorbed during the reaction; and D. Mazzotto found that the heat of soln. of a 0·25 grm. of tin in a gram of mercury is −1·50 Cals. ; with 4 grms. of tin, −3·62 Cals. ; with 0·25 grm. of mercury and a gram of tin, −0·89 Cal. ; and 10 grms. of mercury and a gram of tin, −7·70 Cals. H. W. B. Roozeboom and W. J. van Heteren gave 1000 cals. for the heat of soln. of a gram-atom of tin in mercury at 25°. R. Böttger made tin amalgam by immersing sodium amalgam in a conc. soln. of stannous chloride ; J. Schumann treated sodium amalgam with a soln. of stannic chloride ; and A. C. Becquerel used the process they employed for copper amalgam. J. P. Joule made the amalgam electrolytically with a mercury cathode. He also found that the proportion of tin in tin amalgam can be augmented by strong compression ; an amalgam richer in mercury oozes out. According to E. N. Horsford, the liquid amalgam which drops from a rod of tin sat. with mercury contains 1·55 per cent. of tin.

According to H. W. B. Roozeboom and W. J. van Heteren, liquid tin and mercury are miscible in all proportions, and the temp. at which such mixtures solidify rise from tin to mercury forming two curves ; the first extends from 231·6° to −34·5° for conc. ranging from 100 to −0·3 at. per cent. of tin ; and the second from −34·5° to −38·6° for conc. with 0·3 to 0 at. per cent. of tin—Fig. 56. The first curve is almost a straight line until 120°, when it gradually bends until 40° is attained, at which point it falls almost vertically with the temp. axis. Consequently, at low temp., the amount of tin in the sat. liquid amalgams is very small. Liquid amalgams represented by this curve deposit either pure tin or tin associated with very little mercury. The solid phase at 25° contained 94 per cent. of tin. On cooling

FIG. 56.—Fusion Curves of Alloys of Mercury and Tin.

the amalgams containing 0·3–85 per cent. of tin to −34·5°, a change takes place which is accompanied by a development of heat and a diminution of vol. The maximum change occurs when the amalgam contains about 50 per cent. of tin. All amalgams containing up to 60 per cent. of tin solidify finally at −38·6°. Between −34·5° and −38·5°, mixed crystals separate and expansion takes place. It has not been found possible to determine what modification of tin is then

deposited, but its sp. vol. must be smaller than that of grey tin and larger than that of the ordinary variety. Observations on the f.p. of tin amalgams were also made by E. Wiedemann, N. A. Puschin, R. A. Joyner, G. Tammann, D. Mazzotto, G. McP. Smith, A. Battelli, F. Guthrie, H. V. Regnault, H. Behrens, C. T. Heycock and F. H. Neville, K. Bornemann, and L. Schüz. A compound $HgSn_8$ was reported by E. N. Horsford, but there is no evidence of the formation of chemical individuals. The alloys, said N. A. Puschin, are isomorphous mixtures; and no evidence of the formation of chemical compounds can be obtained from the microstructure.

A. Battelli said that amalgams with more mercury than the atomic proportion Hg_4 : Sn are liquid at ordinary temp., and those with more tin than Hg_2 : Sn are solid. The amalgam Hg_2 : Sn is very soft, and at 100° is quite fluid. According to S. Lucas, the amalgam with one part of mercury and 4 parts of tin gives a kind of mosaic silver when pulverized, and it acquires a metallic lustre when rubbed with a polishing stone. According to L. J. M. d'Aubenton, tin amalgam has the colour of tin if the mercury be not in excess, and it then crystallizes in cubes. F. Hauser studied the microstructure. H. Behrens found that an amalgam with 10 per cent. of mercury is harder than tin, and can be filed; and when broken the fractured surface shows under the microscope stumpy six-sided prisms; under similar conditions, an amalgam with 20 per cent. of mercury shows octahedral crystals. C. von Simson studied the X-radiograms of the tin-amalgams, and found they gave hexagonal space-lattices. G. Tammann and Q. A. Mansuri measured the hardness of tin amalgams. Observations on the fracture were made by N. A. Puschin, J. Schumann, J. P. Joule, F. C. Calvert and R. Johnson, J. H. Croockewit, and J. P. Joule. The sp. gr. of some amalgams measured by R. H. Weber at 17°/17° were :

| Tin (per cent.) | . | . | . | 37·141 | 49·873 | 71·987 | 82·560 | 100 |
| Sp. gr. | . | . | . | 10·475 | 9·684 | 8·418 | 7·959 | 7·390 |

and, according to T. W. Richards and J. H. Wilson, at 20°, amalgams with 0·21, 0·30, and 0·45 per cent. of tin had the respective sp. gr. 13·529, 13·519, and 13·513. Observations on the sp. gr. were also made by A. T. Kupffer, F. C. Calvert and R. Johnson, J. P. Joule, P. I. Bachmetéeff, F. C. Henrici, J. H. Croockewit, A. Matthiessen, and C. Cattaneo. In most cases, said A. T. Kupffer, condensation occurs when the amalgam is formed. E. von Maey represented the sp. vol. of an amalgam with p per cent. of mercury $0·07366 + 0·0006345p$. G. Tammann and K. Dahl measured the vol. changes with ageing. N. A. Puschin said that amalgams with a small proportion of mercury are harder than tin, but with increasing proportions of mercury they become softer. G. Tammann and co-workers measured the hardness of tin amalgams. Rods with 30 at. per cent. of mercury break very easily. L. Schüz also found that rods with between the at. proportions Hg : Sn =2 : 1 and 1 : 5 fracture readily. W. C. Roberts-Austen, and W. J. Humphreys studied the diffusion of tin in mercury. H. Feninger measured the viscosity of the tin amalgams; and E. von Schweidler found the viscosity coeff. for an amalgam with one per cent. of tin to be 0·01630–0·01658 at 20°. G. Meyer found the surface tension of an amalgam with 0·0796 per cent. of tin, in the presence of sulphuric acid of sp. gr. 1·0559, to be 47·8 dynes per cm. F. Schmidt also measured this constant; and C. Cattaneo, and C. Köller, the thermal expansion of tin amalgams. L. Schüz gave for the sp. ht. of the amalgams with the at. ratio :

Hg : Sn	.	.	2 : 1	1 : 1	1 : 2	1 : 3	1 : 4	1 : 5
Sp. ht.	.	.	0·03940	0·04083	0·04218	0·04605	0·04800	0·05039
Temp. to 15°	.	−23°	−30°	−24°	−23°	−30°	−16°

J. Marttinen and J. R. Tiihonen, and H. V. Regnault also measured the sp. ht. of tin amalgam. Observations on the m.p. of tin amalgams have been indicated in connection with Fig. 56; similarly also on the mol. lowering of the f.p. C. Barfoed noted that the tin amalgams on old mirrors give off mercury vap. E. de Souza found that the mercury is not expelled at 360°, but is driven off at 440°; and

V. Merz and W. Weith found the mercury is expelled in 6 hrs. at 445° ; in 15 hrs. at 357° ; and in 92 hrs. at 310°. A. Sieverts and H. Oehme measured the vap. press. in mm. of mercury for a number of amalgams with

Per cent. Hg				0·84	1·30	2·43	4·97	8·00	10·0
At 305°	.	.	.	4	11	14	31	50	—
At 345°	.	.	.	14	20	38	81	119	—
At 358°	.	.	.	—	25	—	90	136	—
At 528°	.	.	.	—	—	—	—	—	886

W. Ramsay also measured the mol. raising of the vap. press. and obtained numbers corresponding with a monatomic mol. J. H. Hildebrand and co-workers found the vap. press., p, of tin amalgams with n mols of mercury per mol of tin, at 324°, $\log (p/p_0) = \log N + 0·220/(0·26 + 0·26n)^2$, where N denotes the molar fraction of mercury, and p_0, the vap. press. of mercury at 324°. A. Coehn and A. Lotz found tin amalgam to be electronegative towards glass. G. Tammann and E. Ohler found that the at. heat of soln. of tin in mercury is -2541 cals. at 14°, and -3148 cals at 97°. For the soln. of tin in dil. gold amalgam the at. heat of soln. is 12,090 cals. greater than in mercury alone. G. Tammann and E. Ohler measured the heat of soln. of tin in mercury. A. Matthiessen and co-workers measured the electrical conductivity of tin amalgams at 18°. R. H. Weber gave for the sp. resistance, R, at 16° referred to that of mercury unity :

Sn	.	.	0	1·399	16·805	24·057	49·873	71·987	82·560	100	per cent.
R	.	.	1	0·880	0·581	0·479	0·285	0·230	0·195	0·123	

He also measured the resistance at 275°, and found :

Sn	.	.	0	4·606	9·292	17·89	43·75	68·81	84·74	100	per cent.
R	.	.	1	0·698	0·614	0·550	0·478	0·434	0·419	0·394	

Measurements were also made by G. G. Gerosa, H. Feninger, A. Battelli, G. Tammann and K. Dahl, F. C. Calvert and R. Johnson, C. Michaelis, R. Sabine, W. Siemens, R. S. Willows, A. Larsen, A. Lohr, C. L. Weber, G. Vicentini, and R. S. Willows. The e.m.f. of the cell $Sn \mid N\text{-}SnCl_2.2H_2O \mid Hg.Sn_n$ was measured by N. A. Puschin, but no evidence of the existence of chemical individuals was obtained. H. P. Cady measured the electrolytic potential of tin amalgams in soln. of potassium stannate ; V. Rothmund, in $0·01N\text{-}SnCl_2$ and $N\text{-}HCl$; W. J. van Heteren found that the difference of potentials between mercury and tin amalgam at 25° is 556·5 millivolt ; and C. Hockin and H. A. Taylor measured the e.m.f. of $HgSn_n \mid ZnSO_4 \mid HgZn$. Observations on this subject were made by J. H. Hildebrand, S. Lindeck, W. J. van Heteren, F. Haber, A. Oberbeck and J. Edler, T. W. Richards and J. H. Wilson, G. Meyer, and G. Gore. R. Kremann and A. Kapaun studied the electrolysis of the tin amalgams, and found the tin accumulates about the cathode. L. Arons found the tension of the electric arc with tin amalgam is greater than with mercury alone. The thermoelectric properties were measured by A. Battelli.

According to W. Ramsay, tin amalgams are stable in air ; but S. Lucas said that if a soln. of one part of tin in 6000 of mercury be shaken in air, the liquid becomes covered with a black film. C. F. Schönbein showed that no hydrogen dioxide is formed when a liquid amalgam is shaken for a long time with water and oxygen or air ; but the dioxide is formed rapidly if water acidified with sulphuric acid be employed. According to C. Brame, if sulphur be allowed to stand a few cm. above tin amalgam, some mercuric sulphide is formed ; L. Brault and A. B. Poggiale showed that when tin amalgam is heated with sulphuric acid, the whole of the tin is dissolved and the mercury remains unattacked. G. S. Sérullas found that potassium amalgam and water separate tin from tin amalgam. A. S. Russell and D. C. Evans studied the efficiency of tin-amalgam in reducing soln. of ferric sulphate, potassium permanganate, and uranyl sulphate, and interpreted the results in terms of the overvoltages.

Tin amalgam is used for silvering mirrors. G. Harrison said that the ordinary amalgam used for this purpose has 83·78 per cent. of tin. J. C. Bull and R. E. M. Lagerwall recommended alloying a little mercury with some of the white metals—Pb–Sb–Sn alloys—*vide supra*, Sn–Ag alloys. R. A. Joyner and W. A. Knight made a partial study of the ternary system Ag–Sn–Hg at 63°, 90°, 166°, and 214°. They said there is no eutectic since the solubilities of tin and silver both become immeasurably small well above the f.p. of mercury. There is a sharp transition point near 70° corresponding with the formation of **mercury hexargentodistannide,** $HgAg_6Sn_2$, or $Hg(Ag_3Sn)_2$. The results at 63° and 214° are shown in Figs. 57 and 58. The field A includes liquids ; B, liquids
FIG. 57.—Equilibrium Diagram of the Ternary System Ag–Sn–Hg at 63°.
FIG. 58.—Equilibrium Diagram of the Ternary System Ag–Sn–Hg at 214°.

and solid soln. represented by a corresponding point on the solidus curve ; D, a sol of the substances represented by the angular points of the triangle D ; E, a sat. soln. of tin and silver in mercury ; F, a soln. of the substances represented by the angular points of the triangle F ; and G, a solid soln. of tin and silver in mercury—*vide* tin-silver alloys. G. Tammann and K. Dahl also studied the ternary system. The volume and other changes which accompany the amalgamation of the tin-silver alloys have been discussed by A. W. Gray, G. Tammann and K. Dahl, G. V. Black, J. W. McBain and R. A. Joyner, W. A. Knight and R. A. Joyner, A. Fenchel, and C. Köller. G. Tammann and Q. A. Mansuri studied the hardness of the ternary alloys. G. Tammann and W. Jander measured the tension for the magnesium-tin and cerium-tin amalgams. R. Kremann and co-workers studied the electrolytic potential of the ternary system : Hg–Cd–Sn.

§ 10. Alloys of Tin with Aluminium, Indium, Thallium, and Cerium

Tin and aluminium readily form alloys; and small amounts of either metal profoundly modify the properties of the other. H. Debray [1] found that aluminium is hardened but made brittle by alloying with a little tin. E. Wetzel showed that tin alloyed with up to 1 per cent. of aluminium becomes brittle in a few days and can be crumbled into fragments. W. C. Anderson and G. Lean found that molten tin and aluminium can be mixed in all proportions. The alloy should be made in fireclay crucibles, but carbon crucibles are suitable. E. Self, A. Riche, and H. Moissan made these alloys. C. R. A. Wright said that when the molten metals have been well mixed by stirring, there is no noticeable tendency for them to separate. L. Guillet made the alloys by reducing stannic oxide with aluminium; and J. Walter electrolyzed molten sodium aluminium chloride using a carbon anode and a tin cathode. The fusion curves have been studied by C. T. Heycock and F. H. Neville, R. Lorenz and D. V. Plumbridge, A. G. C. Gwyer, L. Losana and E. Carozzi, H. Gautier, W. Campbell and J. A. Mathews, L. Guillet, E. S. Shepherd, E. Kordes, and E. Crepaz. The general result is indicated in Fig. 59, showing that the result is comparatively simple. H. Gautier, and L. Guillet give a curve with a maximum corresponding with *aluminium stannide*, AlSn. As A. W. Smith has shown, the electrical conductivity curves for other physical properties give no indication of this compound; but A. Saposhnikoff found a maximum in the hardness curve corresponding with AlSn. H. Gautier considered that the f.p. curve indicates the existence of *aluminium hemitristannide*,

FIG. 59.—Fusion Curves of the Binary System: Al–Sn.

Al_2Sn_3; and F. Guillet claimed to have made *aluminium tetritastannide*, Al_4Sn. The chemical individuality of these products has not been established. E. S. Shepherd gave for the sp. gr. of the aluminium-tin alloys when that of aluminium alone is 2·68:

Al	90	80	70	60	50	40	30	20	10	5 per cent.
Sp. gr.	2·845	3·001	3·211	3·489	3·829	4·199	4·671	5·306	6·176	6·679

C. H. Hirzel, and K. Bornemann and F. Sauerwald also made observations on the sp. gr. A. Saposhnikoff gave for the hardness, *H*, of these alloys:

Sn	.	.	.	0	10	20	30	40	50	60	70	80	90
H	.	.	.	21·7	21·0	18·2	15·8	17·7	16·5	15·4	15·0	18·0	16·3

H. Schirmeister measured the tensile strength; A. W. Smith, the thermal conductivity; and A. Matthiessen, and W. Broniewsky, the electrical conductivities of these alloys, and his results are indicated in Fig. 59; M. Herschkowitsch made observations on the electrode potential; R. Kremann and J. Dellacher, on the electrolysis of these alloys; H. Pécheux, on the thermoelectric force as plotted in Fig. 60.

H. St. C. Deville stated that alloys containing a small proportion of tin can be used for soldering aluminium; M. Bourbouze recommended an alloy with 9–10 per cent. of tin for the interior parts of optical instruments in place of brass. L. Schlieffarth said that this alloy had a tensile strength of 14 kgrms. per sq. mm., and an elongation of 6 per cent. C. and A. Tissier said that an alloy with over

7 per cent. of aluminium is not homogeneous. The uses and properties of the aluminium-tin alloys have been discussed by J. W. Richards, C. Margot, and W. Campbell and J. A. Mathews. According to A. Riche, alloys with 15–50 per cent. aluminium are attacked by water at ordinary temp. with the evolution of hydrogen; H. Moissan could not confirm this; but W. C. Anderson and G. Lean found that the statement is correct, and if the alloy has stood for some time at a high temp., the speed of attack is reduced. H. Péchaux said that when fresh filings of tin-aluminium alloy are immersed in cold distilled water hydrogen is evolved, the oxygen of the water oxidizes the aluminium. With distilled water, 2 c.c. of an alloy $Al_3 : Sn$ produce 5–6 c.c. of hydrogen in 20 mins.; and with a soln. of copper sulphate of sp. gr. 1·1, 5 c.c. of hydrogen are evolved in 20 mins. Old filings are not so active. He said that the phenomenon is due to the juxtaposition of the mols. of each metal; the sp. hts. of aluminium and tin are very different, and the action of the file raises the mols. of each metal to different temp., a series of thermoelectric-couples is accordingly formed when the filings are placed in water. For the change which occurs on ageing, vide supra, the tin-silver alloys. J. W. Richards described a strong malleable alloy with 10 per cent. aluminium, which, after standing for a few months, lost all its malleability and became as rotten as dried clay; annealing did not restore its strength. If the temp. of a piece of alloy in the form of sheet be gradually raised, small globules sprout out in all directions, but these have the same composition as the alloy. E. Heyn and E. Wetzel found that the length of a sample of tin with 0·5 per cent. of aluminium decreased for 28 days after quenching and then increased, but at a slower rate, for the next 150 days.

FIG. 60.—The Electrical Conductivity and Thermoelectric Power of the Tin-Aluminium Alloys.

M. Wählert,[2] D. Stockdale, and A. A. Read and R. H. Greaves studied the Cu–Sn–Al alloys. E. S. Shepherd studied the ternary alloy Au–Sn–Al; and C. T. Heycock and F. H. Neville, E. S. Shepherd, and W. C. Geer, the ternary alloys: Au–Sn–Cd. Evidence of gold cadmium distannide, $AuCdSn_2$, and of gold dicadmium stannide, $AuCd_2Sn$, was obtained by C. T. Heycock and F. H. Neville; but no evidence of $AuCdSn_3$ or of $AuCdSn_4$ was obtained by E. S. Shepherd. The ternary alloys Al–Zn–Sn were studied by E. Crepaz, and L. Losana and E. Carozzi. The fusion curves are shown in Fig. 61. C. R. A. Wright investigated the Sn–Cd–Al alloys; W. Campbell, the Sn–Al–Sb alloys; and C. R. A. Wright, the Sn–Al–Bi alloys.
FIG. 61.—Fusion Curves of the Ternary System: Sn–Al–Zn.

Indium rapidly dissolves in molten tin. C. T. Heycock and F. H. Neville[3] measured the f.p. of tin-indium alloys with only small proportions of indium; and similarly also with the tin-thallium alloys. W. Crookes, and E. Carstanjen made alloys of tin and thallium, and found them to be fusible and ductile. C. T. Heycock and F. H. Neville measured the effect of thallium on the f.p. of tin; and the subject was discussed by K. Bornemann. N. S. Kurnakoff and N. A. Puschin gave 170·2° for the eutectic temp. when $Sn : Tl = 2·2 : 1$. P. Fuchs found the eutectic to be at 166° with 30 at. per cent. of thallium, Fig. 62. The eutectic line extends from 0 to 73 at. per cent. of thallium; with a greater proportion of thallium the alloy forms homogeneous, solid soln. Alloys with less than 73 per cent. of thallium show, on cooling, in addition to the arrest point at the eutectic temp., a second arrest at

144·5°. This arrest point represents the transition point of thallium, lowered through the influence of the tin from about 231°, the transition point of pure thallium. In the solid soln. region, that is, from 73 to 100 per cent. of thallium, the transition point is lowered approximately in proportion to the amount of tin present. The arrest point at 144·5° is the transition point of solid soln. containing 73 at. per cent. of thallium. A. Matthiessen and C. Vogt measured the electrical conductivity of these alloys. The e.m.f. of tin-thallium alloys was found by R. Kremann and A. Lobinger to show no signs of a compound. D. Omodei found an alloy with 30 per cent. of thallium melted at 186°; it had

Fig. 62.—Fusion Curves of the Thallium-Tin Alloys.

a sp. gr. 8·054 when solid and 7·786 when molten; and a coeff. of thermal expansion of 0·0001184. E. Carstanjen studied ternary mixtures of tin, thallium, and bismuth.

R. Vogel[4] prepared *cerium-tin alloys* by heating the mixed metals in a carbon tube previously heated to 1400° without any protecting gas. E. Kordes studied the eutectic mixtures. The f.p. curve, Fig. 63, rises with increasing amount of tin, reaching a maximum at 1400° and 30 per cent. Sn, corresponding with **cerium hemistannide,** Ce_2Sn. There is a second maximum at 1165° and 56 per cent. Sn, corresponding with **cerium hemitristannide,** Ce_2Sn_3, and a third at 1135° and 64 per cent. Sn, due to **cerium distannide,** $CeSn_2$. G. Tammann and W. Jander measured the surface tension of cerium-tin amalgams. R. Vogel found that the alloys rapidly tarnish even when polished and examined under petroleum, but it is possible to recognize the compounds as homogeneous and to detect the eutectic structure in other alloys of the series. All the alloys containing less than 80 per cent. Sn are pyrophoric, especially those containing the hemistannide, mere scratching with a hard object producing a shower of sparks.

Fig. 63.—Freezing-point Curves of Tin-Cerium Alloys.

This compound has also the maximum hardness, of about 6, is very unstable in air, and reacts very vigorously with water. The Kemet Laboratories found that *tin-zirconium alloys* were pyrophoric.

§ 11. Stannous Oxide and Hydroxide

" 'Tis well known to chymists," said Robert Boyle,[1] " that tin calcined by fire alone affords a white calx." In 1792, B. Pelletier first showed that tin forms two oxides with different proportions of oxygen—**stannous oxide, or tin monoxide,** SnO; and *stannic oxide, or tin dioxide*, SnO_2—and the conclusion was subsequently confirmed by the work of J. L. Proust. A third oxide intermediate between these two oxides—namely, *tin sesquioxide, tin hemitrioxide*, Sn_2O_3, or *stannous stannate*, $Sn(SnO_3)$—was reported by J. J. Berzelius. A. Ditte reported *tin tritatetroxide*, Sn_3O_4; H. Schiff, $Sn_7O_{13}.H_2O$; and E. Frémy and G. Tschermak, Sn_8O_{15}. W. Spring obtained *tin peroxide*, $2SnO_3.H_2O$, or $H_2Sn_2O_7$. S. Tanatar reported the peroxides $H_2Sn_2O_7.3H_2O$, and $HSnO_4.2H_2O$. J. Cameron also reported four-sided, prismatic crystals of *tin tetroxide*, SnO_4, occurring in the slag of a copper furnace. Their sp. gr. was 2·8–3·0. There is no confirmation of this oxide as a chemical individual.

The preparation of stannous oxide.—Stannous oxide is obtained by adding an alkali to a soln. of a stannous salt, and boiling the mixture so as to convert the hydroxide into crystalline oxide. For example, J. J. Berzelius prepared the oxide by adding an excess of potassium carbonate to a soln. of stannous chloride; quickly washing the precipitate with thoroughly boiled water so that as little air as possible comes in contact with the precipitate; drying the product below 80°; and dehydrating the oxide by heating it in an atm. of carbon dioxide or hydrogen. J. L. Gay Lussac added an excess of ammonia to a soln. of stannous chloride and boiled the mixture until the stannous hydroxide was transformed into black stannous oxide which was rapidly washed and dried. According to A. Ditte, ammonia does not cause the dehydration of the hydroxide, but actually prevents

it taking place. If the anhydrous oxide be formed, it is only after the ammonia has been expelled by boiling; and if the ammonia be replaced as it is given off by the soln., and the soln. be kept alkaline, no dehydration occurs, however long the soln. be boiled. E. Frémy used a modification of this process; and A. E. Nordenskjöld boiled potassium hydroxide with an excess of a soln. of stannous chloride until the precipitate passed into crystalline anhydrous stannous oxide—*vide infra*. E. Frémy obtained a reddish-brown oxide by precipitating stannous chloride with ammonia and boiling some time; but F. W. Bury and J. R. Partington were unable to obtain the coloured product. If an excess of alkali is used to precipitate the hydroxide, the colour darkens, becoming almost black. O. W. Brown and C. O. Henke made observations on this subject. W. G. Mixter added sodium hydroxide to a soln. of 400 grms. of stannous chloride in 4 litres of hot water, and heated the mixture many days on a water-bath. The precipitate was washed, dried at 100°, and heated to 400° in an atm. of carbon dioxide until no more water was given off. W. Fränkel and K. Snipischsky dissolved stannous chloride in the least amount of hot conc. hydrochloric acid, and gradually added a soln. of sodium hydroxide until the soln. reacted alkaline towards phenolphthalein; the resulting milky liquid was then kept boiling in a bath of sat. sodium chloride soln. In a few hours a blue, lustrous powder was obtained; this was then washed and dried.

S. A. Sandall triturated in a mortar a mixture of a mol of fused stannous chloride and more than a mol of hydrated sodium carbonate; and heated the fluid mass in a basin with constant stirring until it became black. The sodium chloride was washed out with boiling water, and the product dried at a gentle heat. R. Böttger obtained good results and A. Wagner poor results by this process. R. Roth recommended transforming the hydrated stannous oxide into reddish crystalline anhydrous oxide by digesting it with an excess of acetic acid of sp. gr. 1·06 at 56°. J. von Liebig made the anhydrous oxide by calcining stannous oxalate out of contact with air; A. Vogel emphasized the necessity for strongly heating the salt, otherwise up to about 4 per cent. of carbon dioxide may be retained. L. Varenne added potassium cyanide to a soln. of a stannous salt, and boiled the mixture many days to convert the precipitate into crystalline stannous oxide. E. J. Maumené found that when powdered or granular tin is treated with nitric acid corresponding with $HNO_3.4H_2O$, ammonia, and stannous oxide are formed, and that most of the latter remains undissolved.

The properties of stannous oxide.—The appearance of stannous oxide varies with the mode of the preparation. The **colour** may be black, bluish-black, slate-grey, red, green, or greenish-brown. According to E. Frémy, when the hydrate is boiled with a quantity of potassium hydroxide not sufficient to dissolve it, the undissolved portion is converted into small, hard, shining, black crystals of the anhydrous oxide. When heated to 200°, these crystals are converted into an olive-green powder of the anhydrous oxide; when a dil. soln. of ammonium chloride in which hydrated stannous oxide is suspended is evaporated until the ammonium salt crystallizes, the anhydrous oxide furnishes a cinnabar-red powder, which, by friction with a hard body immediately passes into stannic oxide. Hence, added E. Frémy, there are three modifications of stannous oxide, the black crystals, the olive-green, and the red. The red oxide quickly turns black when exposed to sunlight. The olive-green form seems to be the most stable. According to A. E. Nordenskjöld, and L. Varenne, the **crystals** are singly refracting. The hexahedral and octahedral forms belong to the cubic system. G. R. Levi said that stannous oxide has really a tetragonal structure isomorphous with red plumbous oxide, and having the axial ratio $a : c = 1 : 0.895$. The **X-radiogram** corresponds with a lattice having $a = 5.33$ A., and $c = 4.77$ A. J. J. Berzelius and J. Herapath gave 6·666 at 16·5° for the **specific gravity** of stannous oxide; E. Frémy, 6·11; and A. E. Nordenskjöld, 6·04–6·16 at 16°. G. R. Levi gave 6·53 for the sp. gr. According to A. Ditte, the small black crystals obtained by using a very dil. potash-

lye have a sp. gr. 6·600 at 0°; if conc. potash-lye is used, the deep bluish-black crystals have a sp. gr. 6·3254 at 0°, and the dark green plates from a hot soln. of ammonium chloride have a sp. gr. 5·979–6·1083 at 0°; the oxide which has been calcined at 300° has a sp. gr. 6·4465 at 0°. E. Tiede and E. Birnbräuer observed no fusion or volatilization in the cathode rays. W. R. Mott estimated the b.p. to be 1000°; but this is much too low. T. Maeda found that at 700°–950°, stannous oxide is unstable; and decomposes into tin and stannic oxide. W. G. Mixter gave for the **heat of formation**: $Sn_{cryst.} + O = SnO_{cryst.} + 66·8$ Cals.; T. Andrews, 67·6 Cals.; M. Delépine and L. A. Hallopeau, 70·7 Cals.; and G. Chaudron, 69 Cals. E. Friederich found the **electrical conductivity** of stannous oxide to be 150×10^{-6} mho. J. Ewles observed a whitish **cathodoluminescence** with stannous oxide. S. Meyer gave for the **magnetic susceptibility** $-0·158 \times 10^{-6}$ units per gram, or $-0·012 \times 10^{-6}$ units per mol.

J. J. Berzelius found that when heated in an atm. of **hydrogen,** stannous oxide is reduced to the metal. According to A. Ditte, stannous oxide is not changed in **air** at ordinary temp. Stannous oxide is very readily oxidized to stannic oxide. According to R. Weber, when heated in air, or brought in contact with a red-hot substance, stannous oxide glows like tinder, forming a fine, amorphous, pulverulent stannic oxide. A. Ditte showed that stannous oxide is not changed when heated to 300°–310° in the absence of air, but the sp. gr. rises from 6·3254–6·4465. At a red heat, in vacuo or in an atm. of an indifferent gas, a greenish-grey powder is formed with the composition Sn_3O_4. According to L. Wöhler and O. Balz, the equilibrium constant for $[SnO]/[Sn] = 10·6$ at 800°; and for $[SnO]/[SnO_2] = 18·7$. H. Rose reported stannous oxide to be insoluble in **water.** A. Ditte showed that with water vapour at a red heat, stannous oxide forms stannic oxide. R. Weber found that when heated in **chlorine,** stannic oxide and chloride are formed. M. Berthelot said an oxychloride may also be produced. Stannous oxide is soluble in **acids,** forming stannous salts. J. B. Senderens said that when boiled with water containing **sulphur** in suspension, stannous oxide is not changed; but when stannous oxide is melted with sulphur, stannic sulphide and sulphur dioxide are formed. According to D. L. Hammick, when stannous oxide is heated in an atm. of **sulphur dioxide,** the interaction is attended by incandescence, and clouds of sulphur are formed: $18SnO + 7SO_2 = 16SnO_2 + 2SnS + 5S$; and the pale brown mixture of stannic oxide and stannous sulphide passes into stannic oxide, oxide and stannous sulphide. There is probably a secondary reaction $SnS + 3SnO_2 = 4SnO + SO_2$, but no sulphur trioxide was formed. R. Weber said that **nitric acid** converts stannous oxide into metastannic acid; L. H. Milligan and G. R. Gillette examined the reduction of nitric acid by stannous salts. P. Sabatier and J. B. Senderens showed that at 400° stannous oxide burns in an atm. of **nitrous oxide,** forming stannic oxide; and at 500°, **nitrogen peroxide** also forms stannic oxide. H. Rose found stannous oxide is slowly dissolved by a boiling soln. of **ammonium chloride.** According to J. J. Berzelius, when heated with strong reducing agents—with **carbon,** or **potassium,** for example—stannous oxide furnishes the metal. H. Moissan also found that **boron** reduces stannous oxide to the metal. L. Kahlenberg and W. J. Trautman, and E. Vigouroux found stannous oxide is reduced by silicon: $2SnO + Si = 2Sn + SiO_2$. According to A. Wagner, when stannous oxide is heated in a stream of **carbon dioxide,** carbon monoxide, and stannic oxide are formed; this reaction also occurs in the presence of sodium carbonate, and it is of importance in view of some of the methods used in preparing stannous oxide. P. Sabatier and A. Mailhe found that when heated in **alcohol** vapour to 340°–350°, it is slowly reduced, forming carbon dioxide and aldehyde. J. N. Pearce and A. M. Alvarado also discussed the catalytic activity of stannous oxide on alcohol vapour. F. de Carli found that stannous oxide reacts with **molybdic oxide** at 400°; with **tungstic oxide** at 265°; and with **vanadic oxide** at 250°. A. Wagner found that when stannous oxide and **potassium nitrate** are heated together in a stream of carbon dioxide, both the carbon

dioxide and the nitrate are reduced. H. Rose said that stannous oxide is not soluble in a dil. soln. of **potassium hydroxide;** but when boiled with a conc. soln. of potassium hydroxide, J. J. Berzelius, and A. Ditte found that the stannous oxide is partly converted into a stannate, and partly reduced to the metal.

The preparation of stannous hydroxide.—This hydroxide is obtained as a white powder by adding an excess of ammonia, or alkali carbonate to a soln. of stannous chloride, the slimy precipitate filters badly, and is washed by suction or decantation. The proportion of contained water depends on the mode of drying. J. L. Proust found 5 per cent. of water in his preparation; but, according to J. J. Berzelius, the precipitate gives up water when gently heated or boiled with water. L. Schaffner found that the precipitate produced by ammonia contained 6·46 per cent. of water —i.e. $2SnO.H_2O$—when dried at 80°; and A. Ditte found that when dried in vacuo over sulphuric acid at 14°, the yellowish-brown powder contained 22·94 per cent. of water—i.e. $Sn(OH)_2.H_2O$—and when heated in thin layers in a porcelain dish at 110°, the hydrate contained 8·87 per cent. of water—i.e. $3SnO.2H_2O$. L. Schaffner regarded the precipitate produced in a soln. of stannous chloride by ammonia as a basic chloride. F. W. Bury and J. R. Partington examined the precipitates obtained by different methods, and inferred that the products are all essentially the same, approximating $3SnO.2H_2O$. No sample was free from chlorine, though in most cases the amount was negligible. S. Ghosh and N. R. Dhar prepared negatively charged colloidal stannous hydroxide. According to H. T. S. Britton, stannous hydroxide begins to precipitate from soln. of stannous chloride, on the addition of alkali hydroxide, when the H·-ion conc. is $p_H=1·9$.

The properties of stannous hydroxide.—The composition of the hydrate of stannous oxide has been previously discussed. Freshly precipitated stannous hydroxide is white; but when dried in vacuo at 110°, it appears as a yellowish-brown powder which becomes reddish-yellow when rubbed. J. Thomson gave for the heat of formation of stannous hydroxide $(Sn, O, H_2O)=68·09$ Cals. J. L. Proust said that the moist hydroxide absorbs oxygen from the air, and is gradually converted into hydrated stannic oxide. The oxidation must be slow because, as F. W. Bury and J. R. Partington stated, no reaction occurs between the moist hydroxide and atm. air at ordinary temp. It is readily dehydrated when heated in vacuo, or in a non-oxidizing gas; or when boiled with water, dil. acids, dil. alkali-lye, etc., as indicated above. F. W. Bury and J. R. Partington said that when stannous hydroxide stands under water, it slowly passes to stannous oxide; but stannous hydroxide does not lose all its water at 160°. A. Ditte found that stannous hydroxide is converted into crystalline stannous oxide by traces of any acid which is capable of forming a stannous salt which, in turn, is capable of being decomposed by boiling water into free acid and oxide. It is therefore assumed that with hydrochloric acid, a little stannous chloride is formed; this reacts with the excess of stannous hydroxide, forming an oxychloride which is decomposed by water into anhydrous stannous oxide less soluble in hydrochloric acid. The regenerated acid commences anew, and the cyclic reactions continue until the dehydration is complete. Hydrobromic, hydriodic, and acetic acids behave like hydrochloric acid, but the conversion of the hydroxide into oxide is not effected by acids which form stable stannous salts—e.g. nitric acid—nor by those giving stable basic salts in contact with water—e.g. sulphuric acid. The dehydration occurs in the presence of salts like stannous chloride, ammonium chloride, etc.; which are partly decomposed by water with the liberation of an acid which can then react cyclically as ·just indicated.

F. W. Bury and J. R. Partington found the undried hydroxide slowly blackens when kept under water and exposed to light. When suspended in water and two or three crystals of stannous chloride are added, the hydroxide becomes grey, and an olive-green oxide is slowly deposited. When the dried hydroxide is boiled with water and one or two crystals of stannous oxide, a faint salmon-pink colour developed, but this did not darken with further boiling. An excess of stannous

chloride restored the white colour. A. Ditte stated that red, green, and black colours are developed. H. Goldschmidt and M. Eckardt found stannous hydroxide to be sparingly soluble in water; a litre of water dissolves 0·0000135 mol. J. L. Proust found the hydroxide to be readily soluble in acids, forming stannous salts. F. W. Bury and J. R. Partington observed no change when stannous hydroxide is boiled with very dil. hydrochloric acid. A. Ditte reported several modifications of stannous oxide to be formed by boiling stannous hydroxide with ammonium chloride soln. of different conc. F. W. Bury and J. R. Partington found the product in all cases to be the same, namely, dark grey stannous oxide which is formed slowly when the white hydroxide is kept under water. The various reagents described by A. Ditte are considered to be catalytic agents accelerating the passage of the unstable hydroxide to the oxide. Undried stannous oxide in excess was digested with dil. acetic acid, and the soln. in a desiccator formed a yellow crystalline solid, and is probably stannous acetate containing a little water ; A. Ditte regarded it as a basic acetate. When the undried hydroxide is boiled with water containing a few drops of acetic acid, the colour darkens, and a black precipitate is formed ; the liquid remains yellow. The black precipitate becomes yellowish-white with an excess of acetic acid. There was no sign of the red form described by R. Roth. When undried stannous hydroxide is treated with dil. nitric acid, a soln. is obtained which, when evaporated in a desiccator, furnishes a white porcelain-like mass—probably a basic stannic nitrate—it did not detonate when heated ; was insoluble in cold water ; not completely soluble in boiling water ; and gave no precipitate with mercuric chloride. J. L. Proust showed that when stannous hydroxide is treated with a soln. of an alkali hydroxide, it forms soln. of the **stannites;** but it is insoluble in aq. ammonia, or soln. of alkali carbonates. A. Ditte found that potassium and sodium hydroxides act on stannous hydroxide both in the cold and when heated, but the reaction in complicated, and the resulting product varies according to the temp. and conc. of the soln. According to circumstances, an alkali stannate, a mixture of alkali stannate and stannous oxide or metallic tin, may be produced. When a little potassium hydroxide is added to a mixture of water and stannous hydroxide at ordinary temp., crystals of stannous oxide are formed, and these increase in size until all the hydroxide is transformed. Under these conditions, a little potassium stannite is formed, and this is hydrolyzed by water into stannous oxide, less soluble in the alkali-lye, and potassium hydroxide is regenerated to begin the reaction anew. The cyclic reactions continue until all the stannous hydroxide is transformed into the oxide. Sodium hydroxide acts similarly ; aq. ammonia, as previously indicated, does not dehydrate the hydroxide. J. L. Proust said that when stannous hydroxide is mixed with water and cupric carbonate, carbon dioxide is given off, while stannic oxide and crystals of copper are formed. C. Reichard showed that when warmed with a soln. of arsenious oxide in aq. ammonia or sodium hydroxide, the colour becomes brown owing to the formation of stanniferous arsenic : $3Sn(OH)_2 + As_2O_3 + 6NaOH = 3Na_2SnO_3 + 2As + 6H_2O$.   F. Feigl showed that a soln. of potassium stannite is partly oxidized to stannate by filtration through blood charcoal.

According to A. Hantzsch, the formation of stannites by the dissolution of stannous hydroxide in a not too conc. soln. of alkali hydroxide, corresponds with the presence of monobasic **hydrostannous acid,** $H.SnO.OH$, *stannoformic acid,* analogous to formic acid, $H.CO.OH$. This means that in the stannites, tin is quadrivalent. This conclusion is based on measurements of the electrical conductivities of the hydroxides of beryllium, zinc, germanium, tin, and lead in alkaline soln., and the rates at which these soln. hydrolyze ethyl acetate. The sodium salt thus becomes $H.SnO.ONa$, or **sodium hydrostannite.** Although there is no confirmatory evidence of the direct union of the atom of hydrogen to tin, there are analogous acids—*e.g.* $H.SO_2.OH$, $H_2.PO.OH$, and $H.PO(OH)_2$. H. Goldschmidt and M. Eckardt studied the reducing action of soln. of the alkali stannites, and they agree with A. Hantzsch's view of the constitution of these salts in dil. alkaline

soln., but with conc. soln., they state that normal sodium stannite, Na_2SnO_2, is formed. P. Pfeiffer found that when an aq. alcoholic soln., of the alleged **potassium hydrostannite**, $H.SnO.OK$, is treated with ethyl iodide, the product is not $C_2H_5.SnO.OK$ as would be expected, but *stannyl diethide*, $(C_2H_5)_2SnO$, is formed. According to J. Rubenbauer, soln. of stannous hydroxide in alkali-lye do not contain stannites, but rather a sol. of colloidal hydroxide. The amount dissolved depends on the conc. of the alkali-lye and reaches a minimum when the ratio $Sn:Na=1:7·7$. The minimum is attributed to the dehydration of the hydroxide by the alkali in conc. soln. whereby the hydroxide becomes less soluble. N. R. Dhar and S. Ghosh found that tin hydroxide is peptized by alkali-lye with glycerol, starch, or sugar. W. Herz observed that when an alkaline soln. of stannous hydroxide is dialyzed, the hydroxide passes through without being precipitated on the parchment. This is taken to agree with A. Hantzsch's view that stannous hydroxide is a weak acid. N. R. Dhar found that the oxidation of stannous salts is hindered by the presence of easily oxidized substances like sodium arsenite, quinol, glycerol, and sugars. According to A. Gutmann, sodium or potassium stannite reacts with sodium thiosulphate at ordinary temp. with the formation of stannous sulphide, sodium stannate, sulphite, and sulphostannate. Potassium stannite reacts with sulphur, forming stannous sulphide, which unites with the alkali stannite, forming octahedral crystals of potassium metasulphostannite, $K_2SnS_3.3H_2O$; sodium tetrathionate reacts with a stannite at ordinary temp. forming stannous sulphide, and alkali stannate, sulphite, and sulphostannate; while sodium dithionate has no action at ordinary temp., or in boiling soln.

The stannites are known only in soln. J. L. Proust made a soln. of **potassium stannite** by dissolving stannous hydroxide in a soln. of potassium hydroxide; and a soln. of **sodium stannite** in an analogous manner. G. Lunge made a soln. of potassium stannite by adding solid potassium hydroxide to a mixture of water and washed, freshly precipitated stannous hydroxide. H. Goldschmidt and M. Eckardt obtained a soln. of sodium stannite free from sodium chloride by electrolyzing a conc. soln. of soda-lye with a rotating tin anode, and a platinum cathode, working with a low current density, and protecting the soln. from oxidation in an atm. of hydrogen. According to E. Frémy, if a soln. of potash-lye be sat. with stannous hydroxide and evaporated in vacuo, stannic oxide is precipitated. M. H. Klaproth found that laminæ of tin are precipitated when the soln. of potassium stannite is treated with zinc. According to A. Ditte, the stannites are not stable in conc. soln. of the alkali hydroxides, but are decomposed with the separation either of stannous oxide or of tin, and the formation of the alkali stannate. When stannous hydroxide is dissolved to saturation in a 39 per cent. soln. of potassium hydroxide, stannous oxide separates out, and on standing, oxygen is absorbed and potassium stannate is formed; with a 39–50 per cent. soln., the stannate is rapidly formed owing to the reduction of part of the stannous oxide to tin; when the soln. is allowed to stand both products—potassium stannate, and tin—appear in well-formed crystals. When the soln. of alkali stannate is evaporated these two products are always formed. A. Ditte has discussed the thermochemistry of the change. J. A. Hedvall and N. von Zweigburgk did not observe any reaction between stannous oxide and barium dioxide when a mixture of the two was heated.

Soln. of the alkali stannites are readily oxidized, and the soln. therefore act chemically as reducing agents. Thus, A. Terreil found that Fehling's soln. furnishes a precipitate of cuprous oxide; M. C. Harding, that an alkali soln. of **antimonious oxide** gives a greyish-black precipitate of antimony; and L. Vanino and F. Treubert, that lead is precipitated from soln. of **lead salts**; and bismuth, bismuth trioxide, and bismuth oxychloride from soln. of **bismuth salts**—R. Schneider reported that bismuth monoxide is also formed. E. Divers and T. Haga found that **nitrogen peroxide** is reduced by soln. of alkali stannites to a hyponitrite; and that **nitric oxide** also forms hyponitrite: $K_2SnO_2+2KOH+2NO=K_2SnO_3+2KNO+H_2O$; and

there is an intermediate formation of a nitrostannate, $K_2SnO_2+2NO=K_2(NO)_2SnO_2$. Alkali stannites do not reduce **nitrites** and **nitrates.** A. Gutmann observed that **sodium tetrathionate** is reduced to sodium sulphide, and sulphite, and sodium thiostannate and stannate are formed, while **dithionates are** not changed. H. Goldschmidt and M. Eckardt studied the reduction of **aromatic nitro-compounds** by alkali stannites; and R. Böttger found a conc. soln. of potassium stannite dissolves **gun cotton** but not **cellulose.**

A number of oxides intermediate between stannous and stannic oxides has been reported. A. Ditte heated to redness crystals of stannous oxide in an atm. of carbon dioxide and obtained a pale greyish powder mixed with small globules of tin. The powder had a composition; **tin tetritoxide,** Sn_3O_4, or $Sn(SnO_2)_2$, stannic stannite. It was slowly attacked by cold hydrochloric acid, and rapidly attacked by hot acid leaving a residue containing stannic oxide and tin. There is no evidence supporting the view that this oxide is a chemical individual. According to J. N. von Fuchs,[2] when a slight excess of a soln. of stannous oxide is boiled with freshly precipitated ferric or manganic hydroxide, **hydrated tin sesquioxide,** or *tin hemitrioxide*, $Sn_2O_4.nH_2O$, is formed: $Fe_2O_3+2SnCl_2=2FeCl_2+Sn_2O_3$. The action takes place less quickly in the cold ; and with dried ferric hydroxide the boiling must be prolonged. The precipitate, said J. J. Berzelius, is frequently mixed with ferric hydroxide even after a prolonged washing. J. N. von Fuchs said that if the stannous chloride contains no free acid, a small quantity of iron is dissolved at the beginning of the reaction before any tin sesquioxide is precipitated ; and if the ferric hydroxide be boiled briskly with an excess of stannous chloride, the precipitate which forms at first is redissolved, but reappears on the addition of water, and is then contaminated with a basic chloride. J. N. von Fuchs made the hydrated sesquioxide by mixing soln. of ferric and stannous chlorides, and as soon as the mixture becomes green, adding an excess of calcium carbonate, applying a gentle heat. J. J. Berzelius also made the hydrated sesquioxide by mixing soln. of ferric and stannous chlorides each mixed with as much ammonia as possible without precipitation. The mixture gradually loses its colour, and the sesquioxide is precipitated. When heated in an atm. of carbon dioxide, brownish-black anhydrous **tin sesquioxide,** Sn_2O_3, is formed. The hydrated sesquioxide forms a yellowish-white precipitate which is gelatinous and difficult to wash. J. N. von Fuchs said that with auric chloride it forms a fine purple of Cassius ; and, according to J. J. Berzelius, it dissolves completely in ammonia, and is therefore not merely a mixture of stannous and stannic oxides—the latter does not dissolve in ammonia. L. Gmelin suggested that the sesquioxide is *stannous stannate*, $Sn(SnO_3)$. S. Meyer gave for the magnetic susceptibility -0.614×10^{-6} units per gram, -0.076×10^{-6} units per mol of Sn_2O_3. L. Wöhler and O. Balz found no evidence of the formation of a sesquioxide in their study of the formation and reduction of stannic oxide.

A number of stannous stannates has been reported. E. Frémy digested the so-called metastannic acid for some hours with a soln. of stannous chloride at 40°–50°, and obtained an orange-yellow, insoluble substance with the composition $Sn_4O_7.3H_2O$, or $SnO.3SnO_2.3H_2O$, or *stannous tristannate*. In air or when treated with nitric acid, it forms stannic acid ; with hydrochloric acid, it forms stannous and metastannyl chlorides ; and when heated with a soln. of potassium hydroxide, it forms alkali stannite and stannate. It loses its water at 140° in a current of carbon dioxide or nitrogen. E. Frémy said that an excess of metastannic acid will remove all the tin from a soln. of stannous chloride ; but G. Tschermak was unable to confirm this. H. Schiff reported an orange-yellow hydrated oxide with the composition $Sn_7O_{13}.5H_2O$, or $SnO.6SnO_2.5H_2O$, or *stannyl hexastannate,* to be formed when stannous hydroxide is digested for some hours with a soln. of stannous chloride. E. Frémy heated stannic acid with stannous chloride, and obtained a brown powder with the composition $Sn_8O_{15}.nH_2O$, or $SnO.7SnO_2.nH_2O$, or *stannyl heptastannate.* By working at 50°–60°, H. Schiff obtained a chocolate-brown product with the composition $SnO.20SnO_2.nH_2$, or *stannyl icosistannate.* There is no evidence establishing the chemical individuality of these products; and variation in the composition rather indicates that mixtures are in question.

According to P. Schützenberger, when the product obtained by heating with

hydrochloric acid an alloy of platinum with five times its weight of tin in an inert atm., is treated with warm dil. aq. ammonia, the whole of the combined chlorine is removed, and a hydrated oxide is obtained resembling the chloride in appearance, but with a slight brown colour. When dried in a vacuum over sulphuric acid, it has the composition $Pt_2Sn_3O_4H_2$, or *platinum distannyl stannous hydroxide*, $Pt_2(SnO)_2Sn(OH)_2$, and on reduction by hydrogen it yields a greyish-white, pulverulent, almost fusible alloy of the composition Pt_2Sn_3, identical with that obtained by H. St. C. Deville and H. Debray by melting 1 part of platinum with 6 parts of tin, and treating the cold alloy with hydrochloric acid. In this latter case, it is probable that the large crystals in which the alloy Pt_2Sn_4 was obtained, were only superficially attacked by the hydrochloric acid. If the pulverulent alloy be heated to dull redness in oxygen, combination takes place with incandescence, and the oxide formed has the composition $Pt_2Sn_3O_3$, or *platinum tristannyl*, $Pt_2(SnO)_3$. The reduction and reproduction of this oxide can be repeated any number of times. If the hydrated oxide is heated in a current of dry oxygen, water is given off, but is replaced by oxygen, and an oxide of the composition $Pt_2Sn_3O_4$, or **platinum distannyl stannic oxide,** $Pt_2(SnO)_2SnO_2$, is formed. If, however, this compound is reduced by hydrogen, and the residue reoxidized, the oxide $Pt_2Sn_3O_3$ is alone obtained. These stanno-platinic compounds have considerable catalytic power. They oxidize alcohol into aldehyde, and when the hydrated oxide is brought in contact with hydrogen, there is a considerable development of heat. When the pulverulent alloy Pt_2Sn_3 is brought in contact with chlorine, a large amount of heat is developed, and stannous chloride volatilizes. P. Schützenberger represented these products graphically :

$$OSn=Pt-Pt=SnO \qquad OSn=Pt-Pt=SnO \qquad OSn=Pt-Pt=SnO$$
$$\diagdown\diagup \qquad\qquad \diagdown\diagup \qquad\qquad \diagdown\diagup$$
$$SnO \qquad\qquad HO-Sn-OH \qquad\qquad Sn$$
$$\diagup\diagdown$$
$$O-O$$

$$Pt_2(SnO)_3 \qquad\qquad Pt_2(SnO)_2Sn(OH)_2 \qquad\qquad Pt_2(SnO)_2SnO_2$$

§ 12. Stannic Oxide

The ancients no doubt obtained tin from the native form of **stannic oxide,** or **tin dioxide,** SnO_2. This ore is the *stannum calciforme* of T. Bergman,[1] and the *Zinnstein* of J. G. Wallerius. It is the *tin ore*, or *tinstone* of various mineralogists, *e.g.* C. C. von Leonhard, etc. F. S. Beudant called it **cassiterite.**

The brown ore, found in botryoidal and reniform shapes concentric in structure and with a radiating fibrous structure, was called by R. Kirwan, *wood-tin*, owing to its external resemblance to wood. This was shown by R. J. Haüy, and J. F. L. Hausmann to be a form of tinstone. Wood tin in the upper part of tin lodes and gravel deposits is considered to be an alteration product of stannite or tin pyrites, or bell-metal ore. A Cornish name for small spherical nodules of wood-tin is *toad's-eye tin*. Acute pyramidal crystals of cassiterite are called *needle tin ore ;* and acute crystals from Camborne, Cornwall, are called *sparable tin* in allusion to their resemblance to the so-called sparable nails. The German miner's names for the twinned crystals are *Zwitter*, and *Zinngraupen*. The so-called *stream tin* is cassiterite occurring in the form of sand or pebbles in the beds of streams or in the adjoining gravel ; cassiterite occurring in the soil formed by the disintegration of stanniferous rocks is called *float tin*. The *stannite* of A. Breithaupt is an amorphous, yellowish-white substance from Cornwall, and is a mixture of stannic oxide and other minerals. The *ainalite* of A. E. Nordenskjöld is a cassiterite containing about 9 per cent. of tantalic oxide, found at Pennikoja, Finland ; W. T. Schaller proposed calling it *tantalum cassiterite.*

Analyses have been made by T. Bergman,[2] M. H. Klaproth, F. Gmelin, J. J. Berzelius, E. Charlon, C. Bergemann, J. D. Bruce, A. E. Nordenskjöld, R. J. Meyer, J. W. Mallet, D. Forbes, P. Kröber, F. A. Genth, F. P. Dunnington, W. G. Brown, F. Becke, W. Kohlmann, W. R. Dunstan, T. Petersen, E. S. Simpson, T. Liebisch, A. Breithaupt, J. Königsberger and O. Reichenheim, etc. The results are in agreement with the formula SnO_2. T. Liebisch found the spectroscopic evidence of the presence in cassiterites of copper, calcium, aluminium, silicon, titanium, columbium, tungsten, and iron to be very clear ; that of potassium, strontium, manganese, chromium, molybdenum, tantalum, zirconium, and gallium, more or less clear ; and indium was observed in cassiterite from Zinnwald. G. Eberhardt observed scandium in some samples of cassiterite.

There is evidence that in some cases cassiterite has been formed in nature by crystallization from soln. ; and in other cases by the infiltration of vap. from below. C. Doelter [3] found the oxide is appreciably soluble in water at 80°, particularly if sodium fluoride be present. S. Meunier, for example, found 0·5 per cent. in an

opaline deposit like geyserite, from a thermal spring at Selangor. J. H. Collins observed cassiterite as a cement in some Cornish conglomerates ; as an impregnation in the long-buried horns of a deer ; as pseudomorphs after felspar ; as cappings on crystals of quartz ; as a lining in fissures of quartz ; as an incrustation on an ingot of ancient tin having been formed by slow oxidation ; and as crystals on reniform masses of wood-tin. F. A. Genth observed pseudomorphs of cassiterite after hæmatite ; L. V. Pirsson, as enclosures in crystals of hæmatite ; and E. Wittich, as stalactitic masses at Sierra de Guanajacato, Mexico. This subject has been also discussed by C. Reid and J. B. Scrivener, and J. B. Hill and D. A. MacAlister. The formation of cassiterite veins as a result of the infiltration of stanniferous soln. has been noted by L. K. Ward, F. Sandberger, G. Bischof, W. von Fircks, C. W. Kempton, W. R. Ingalls, E. Halse, J. Nevius, A. H. Bromly, R. A. F. Penrose, R. Beck, etc.

Cassiterite occurs in lodes connected with granite intrusions, or with the volcanic equivalents of granite. The lodes penetrate the granite and surrounding rocks, and mark a late phase in the consolidation of the intrusion, when the fluoriferous and boriferous exhalations altered the granite into *griesen*, and formed minerals like tourmaline, fluorite, etc. Tin commonly occurs in quartz veins in granite, and the felspar of the granite has been transformed into mica (generally lepidolite and zinnwaldite). The boriferous and fluoriferous minerals topaz and tourmaline are also present. These facts agree with the assumption that the ordinary type of tin deposits has been formed by the injection of vapour carrying boron, fluorine, and tin. This hypothesis is confirmed by the syntheses of cassiterite by processes involving the use of boric oxide and of tin fluoride or chloride. Usually the boron forms tourmaline and tin cassiterite, but in the rare mineral nordenskjöldine, the tin and boron occur together. The fluorine is represented by topaz, fluorite, apatite, axinite, triphylite, and amblygonite. This subject has been discussed by A. Daubrée, J. H. L. Vogt, W. Lindgren, H. Schröder, A. W. Stelzner, K. Dalmer, R. Recknagel, F. Gautier, F. Beyschlag and co-workers, G. Steinmann, A. Bergeat, G. Tschermak, J. F. W. Charpentier, K. Dalmer, W. R. Jones, etc. Wolframite and the secondary minerals scheelite and stolzite are commonly associated with cassiterite. Copper sulphides, arsenopyrite, pyrite, and ores of bismuth, uranium, and iron are also found in cassiterite lodes.

When tin is heated nearly to its b.p. in air, it burns with a white luminous flame, and the stannic oxide so formed is in a very fine state of subdivision, and was formerly known as *flores jovis* or *flores stannic—flowers of tin*. When the metal is fused in the presence of air, the surface soon becomes covered with a grey pellicle, which passes into a grey powder known as *tin-ash*, and this consists of a mixture of finely divided metal and oxide which with a prolonged roasting is converted into white stannic oxide. The oxide obtained at a high temp., and in a very finely divided state, is less soluble in fused silicates, and is preferred when stannic oxide is used as an opacifying agent in glazes and enamels; this form of oxide has also a greater opacifying power than the oxide made by many other processes. C. P. Bary[4] recommended blowing heated air over the surface of tin at a high temp.; the Elektrizitäts-Gesellschaft Gelnhausen heated the metal electrically to about 1700° and burnt the tin vap. in air or oxygen; H. Försterling, E. Dechert, M. Wassermann and M. Jäger, etc., also devised analogous processes. V. Kohlschütter and J. L. Tüscher obtained **colloidal stannic oxide** by making tin one electrode of an arc, and oxidizing its vap. by air. In this way, stannic oxide dispersed in a gaseous medium is obtained.

J. L. Gay Lussac, and H. V. Regnault found that amorphous stannic oxide is formed when tin is heated in a current of water vapour. J. L. Proust showed that the lower oxide and hydroxide are transformed, by roasting, into stannic oxide; and that moist stannous oxide is transformed into stannic oxide when exposed to the air for a year. J. J. Berzelius made analogous observations, and he found that stannic oxide is formed by roasting the sulphide, or by heating a mixture of tin and

mercuric oxide. The dioxide is also obtained by treating tin with nitric acid; the reaction is vigorous and the resulting hydrate is a white powder which is washed and ignited. When a soln. of a stannic salt is treated with aq. ammonia, a gelatinous precipitate is obtained which is difficult to wash; but if the mixture be warmed with a conc. soln. of sodium sulphate, the dense precipitate is easily washed, and it furnishes the dioxide on ignition. P. T. Austen made the amorphous dioxide by passing carbon dioxide into a boiling soln. of sodium stannate, or by heating the soln. with sodium hydrocarbonate; and roasting the washed product—vide infra, alkali stannates. A. Vogel made finely divided stannic oxide by heating to redness stannous oxalate in thin layers; and S. J. Lubowsky, by heating tin hydroxide to 1040° sufficiently long to produce the required colour.

M. H. Klaproth [5] melted brown cassiterite from Schlaggenwald in a clay crucible, and observed that pale brown acicular crystals were formed on the inner wall of the crucible. Crystals of stannic oxide of the cassiterite type have been frequently observed among furnace products—e.g. in the scoriæ of brass furnaces—by J. Törmer, W. P. Headden, G. vom Rath, F. A. Abel, K. N. Spallart, A. Arzruni, J. H. L. Vogt, L. Bourgeois, etc. The first synthesis of crystalline stannic oxide was made by A. Daubrée by passing a mixture of steam and stannic chloride vap., or of dry carbon dioxide and stannic chloride vap., through a red-hot porcelain tube. He also made it by passing the vap. of stannic chloride over red-hot calcium oxide. H. St. C. Deville and H. Caron obtained the crystals by passing stannic fluoride and water vap. through a red-hot tube; and H. St. C. Deville, by passing a slow current of hydrogen chloride over red-hot amorphous stannic oxide. H. de Sénarmont obtained crystals of stannic dioxide by heating in a sealed tube a soln. of stannic acid in hydrochloric acid. A. Knop, and G. Wunder observed that a phosphate is formed when a soln. of stannic oxide in microcosmic salt at a white heat is cooled, but with molten borax, crystalline stannic oxide is formed. A. Michel-Lévy and L. Bourgeois obtained the crystals by melting at a white heat a mixture of sodium carbonate and stannic oxide; H. Traube melted the oxide with sodium tungstate along with ferric, manganese, chromic, nickel, or cobalt oxide, and obtained coloured crystals of cassiterite. L. Bourgeois obtained crystals by melting silica, stannic oxide, and calcium chloride at a red heat; and by melting a mixture of tin or stannic oxide with an excess of cupric oxide at a red heat, cooling the mixture slowly, and dissolving out the cuprous oxide with aqua regia; A. Ditte, by heating a mixture of amorphous stannic oxide, calcium chloride, and ammonium chloride; and L. Grandeau, by heating a mixture of tin phosphate and potassium sulphate.

The physical properties of stannic oxide.—Artificial preparations of stannic oxide are white, greyish-white, or colourless; but colourless cassiterite is very rarely found in nature. The **colour** is often yellow, red, or grey; and commonly yellowish- or reddish-brown to black. In some places the red ore is called *ruby tin;* and the yellow ore, *resin tin.* The dark colour is almost always due to the presence of ferric oxide; but F. Becke [6] found only 0·12 per cent. of ferric oxide in the dark brown crystals of Schlaggenwald. J. W. Retgers found that neither ferric oxide nor manganese dioxide forms isomorphous mixtures with stannic oxide, and he called the mixture *eine anomale Mischung.* H. Traube noted that stannic oxide can dissolve a number of colouring oxides—vide supra—and obtained peach-red crystals when chromic oxide is present. W. Kohlmann attributed the colour of the crystals from Perak to the presence of 0·11 per cent. of tungstic oxide, and 0·12 per cent. of ferrous oxide. E. Weinschenk observed the effect of calcination on the colour of the crystals of cassiterite. A. Dittmann found cassiterite from Ehrenfriedersdorf was decolorized at a red heat; and concluded that the pigment was not ferrous oxide; no organic matter distilled off. Thin sections may be colour- less or tinged yellow, brown, or red. The colour may be irregularly distributed in streaks or spots, and sometimes zonally. The lustre is adamantine.

The **crystals** of cassiterite were early described by J. B. L. Romé de l'Isle,[7] R. J. Haüy, W. Phillips, F. Mohs, C. F. Naumann, and W. H. Miller. The crystals

are rarely simple and euhedral, and when such crystals do occur, they may be either stout square prisms, or slender prisms terminated by acute pyramid faces—*needle tin*. Both forms belong to the tetragonal system, and, according to F. Becke, have the axial ratio $a : c = 1 : 0\cdot67232$; S. Stevanovic gave $a : c = 1 : 0\cdot6726$; and L. H. Borgström, $1 : 0\cdot6722$. Cassiterite is usually found in irregularly shaped anhedral crystals; and, as indicated above, it may occur in divergent fibrous masses. Contact and penetration twins are common; the **twinning** and composition plane is (101); repeated twinning may produce complex forms giving a succession of knee-shaped corners in which two striated prism zones meet at angles of 67° 50'. The crystals of cassiterite have been described by P. Groth, A. W. Stelzner, H. von Foullon, A. Arzruni, F. Hessenberg, W. Haidinger, A. Sadebeck, R. Hörnes, A. Pelikan, V. von Zepharovich, A. Lacroix, R. P. Greg and W. G. Lettsom, C. Busz, R. H. Solly, W. Kohlmann, A. Lévy, A. E. Nordenskjöld, M. Bentivoglio, G. Cesaro, H. Baumhauer, A. Gadolin, L. H. Borgström, P. von Jeremejeff, G. vom Rath, A. von Groddeck, W. T. Schaller, S. Stevanovic, E. Artini, etc. G. Rose showed that rutile, zircon, and cassiterite appear to be isomorphous, and P. Groth attributes this to the similarity in their constitutions supposed to be respectively $Ti(TiO_4)$, $Zr(SiO_4)$, and $Sn(SnO_4)$. I.V.Pirsson described pseudomorphs of cassiterite after hæmatite, and J. A. Phillips, after orthoclase. The **cleavage** parallel to (100) is imperfect; that parallel to (111) is less so; and that parallel to (110) is scarcely distinct. F. Becke, and W. E. Hidden observed parting planes or lamellar separations in some crystals. H. Traube studied the **corrosion figures** with molten potassium fluoride or potassium hydrofluoride and obtained results similar to those with rutile and zircon. G. A. Dima studied the **photoelectric effect.** The **X-radiograms** of cassiterite, analogous with those of rutile, have been made by W. P. Davey, L. Vegard, H. Haga and F. M. Jäger, C. M. Williams, N. Yamada, P. F. Kerr, M. L. Huggins, and J. A. Hedvall.

A. Daubrée's artificial crystals [8] were stated to be *rhombic* like brookite, but H. St. C. Deville could not confirm this, and P. Groth also doubted the inference. A Michel-Lévy, and L. Bourgeois' preparation—*vide supra*—was stated to be *hexagonal* like tridymite, but this lacks confirmation. A. Arzruni observed in furnace slags from Talgau, besides cassiterite some small, colourless crystals which he considered to be a *monoclinic* modification of stannic oxide, but P. Groth said that these crystals were probably twinned tetragonal crystals.

R. Boyle [9] gave $4\cdot18$–$5\cdot00$ for the **specific gravity** of tin-ore. Numerous observations have been made on the sp. gr. of cassiterite, and stannic oxide. The values range from D. Forbes' value $7\cdot021$ for a sample from Bolivia to F. A. Genth's value $6\cdot160$ for a sample from Durango—J. W. Mallet found $6\cdot753$; C. Bergemann, $6\cdot862$; P. Kröber, $6\cdot4$; J. Herapath, $6\cdot639$ at $16\cdot5°$; P. Boullay, $6\cdot90$; F. E. Neumann, $6\cdot952$; W. G. Brown, $6\cdot609$; E. P. Dunnington, $6\cdot956$; F. A. Genth, $6\cdot160$–$6\cdot911$; W. R. Dunstan, $6\cdot91$; H. Rose, $6\cdot849$–$6\cdot978$; E. Weinschenk, $6\cdot65$; A. E. Nordenskjöld, $6\cdot6$–$6\cdot8$; and L. Playfair and J. P. Joule, $6\cdot1722$ at 4°. H. Schröder gave $6\cdot85$–$6\cdot98$; and after calcination, $6\cdot89$–$7\cdot18$. The best representative value is $6\cdot95$. D. Forbes reported $6\cdot8432$–$6\cdot8439$ at $15\cdot5°$ for the sp. gr. of colourless cassiterite from Bolivia, $6\cdot704$ at $15\cdot5°$ for a yellow specimen, and $6\cdot7021$ at $15\cdot5°$ for a black specimen. For artificial crystals, A. Daubrée gave $6\cdot72$; and A. Michel-Lévy and L. Bourgeois, $6\cdot70$. S. Stevanovic gave $6\cdot992$–$7\cdot044$ for the sp. gr. of artificial crystals at 16°. J. J. Berzelius gave $6\cdot64$ for the sp. gr. of amorphous stannic oxide, and F. Emich for stannic oxide made by calcining the metal, $7\cdot0096$ at $0°/4°$. The **hardness** on Mohs' scale is 6–7. Artificially prepared stannic oxide is used as a polishing powder for metals, etc. The hardness was discussed by A. Reis and F. Zimmermann. E. Madelung and R. Fuchs found the coeff. of **compressibility** of cassiterite to be $3\cdot38 \times 10^{-12}$ dynes per sq. cm.

The coeff. of **thermal expansion** of cassiterite found by H. Kopp [10] is

$a=0.000004$ between 16° and 46°, and for the coeff. of cubical expansion 0·000016. L. Playfair and J. P. Joule gave 0·0000172 for the coeff. of cubical expansion of stannic oxide between 0° and 100°. F. Pfaff gave for the coeff. of linear expansion in the direction of the a-axis, 0·000004526, and in the direction of the c-àxis, 0·000004860 ; or, for the coeff. of cubical expansion, 0·00001389. H. Fizeau gave for the coeff. of linear expansion at 40° parallel to the c-axis, 0.0_5392, and 0.0_6321 vertical to that axis. For the coeff. of cubical expansion at 40° he gave 0.0_41034. F. E. Neumann gave 0·0931 for the **specific heat** of cassiterite between 0° and 100° ; H. V. Regnault, 0·09326 between 16° and 98° ; and H. Kopp, 0·0894 between 16° and 47°. E. Jannettaz found that if the **thermal conductivity** in the direction of the chief axis is unity, that in a vertical direction is 0·79. H. de Sénarmont made some observations on this subject. E. J. Housten found that when the temp. of white amorphous stannic oxide is gradually raised, it becomes pale green, then yellowish-green, and passes through a chromatic scale to orange or reddish-orange ; on cooling, the order is reversed. E. D. Clarke melted cassiterite in the oxy-hydrogen blowpipe flame, and G. Spezia found that cassiterite was fused when the ordinary blowpipe flame was fortified by using hot air, or oxygen. R. Cusack gave 1127° for the **melting point** of cassiterite ; and A. L. Fletcher, 1177°. O. Ruff and co-workers gave 1625° for the m.p. of stannic oxide contained in a zirconia crucible ; a pyramidal cone of the oxide squats at 1625°. E. Tiede and E. Birn-bräuer observed no fusion or volatilization in the cathode rays. H. Moissan found that in the electric arc furnace cassiterite is fused and volatilized. O. Ruff and co-workers found that at the m.p. stannic oxide decomposes, and at 2250°, the vap. of tin is present. W. Fränkel and K. Snipischky gave 1·66 Cals. for the latent **heat of fusion** of a mol of stannic oxide. T. Maeda found the **dissociation pressure** of the oxygen by stannic oxide at 927° is 4.47×10^{-15} ; and the heat of formation $(Sn_{liquid}, O_2)=130.26$ Cals. at 800° ; W. Fränkel and K. Snipisch-sky gave 135·8 Cals. from solid tin and 137·46 from molten tin. W. Rosenhain gave 2350 cals. per gram for the **heat of formation** of stannic oxide from tin-foil ; W. G. Mixter gave $(Sn, O_2)=137.8$ Cals. for the crystalline oxide ; T. Andrews obtained a similar number ; and J. E. Moose and S. W. Parr gave 138·2 Cals. L. Vignon found the **heat of neutralization** with potassium hydroxide to be 1·0 Cal. for stannic oxide which has been calcined at a red heat, and 4 Cals. for the oxide obtained by boiling a stannic salt with a soln. of sodium sulphate.

The **index of refraction** and **birefringence** of cassiterite are strong. T. Liebisch[11] observed that the index of refraction of the strongly coloured parts of a crystal is greater than in the feebly coloured parts. H. Rosenbusch gave for the indices of refraction of a crystal from Schlaggenwald :

	Red.	Yellow.	Green.
ω	1·9793 (1·9765)	1·9966 (1·9923)	2·0115
ϵ	2·0799 (2·0748)	2·0934 (2·0911)	2·1088

The bracketed numbers refer to a crystal from Zinnwald. A. Arzruni found for artificial violet crystals $\omega=1.9850$ and $\epsilon=2.0817$ for the red ray ; $\omega=1.9965$ and $\epsilon=2.0991$ for the yellow ray ; and $\omega=2.0093$ and $\epsilon=2.1045$ for the green ray. The **optical character** is positive. A. Ehringhaus and H. Rose studied the relation between the mol. wt. and the dispersion or birefringence. A. Madelung observed that crystals from Breitenbrunn appeared to be biaxial, and are therefore **optically anomalous.** The **pleochroism** of the crystals of cassiterite is usually feeble, and has been observed by H. Traube, H. von Foullon, A. Lacroix, A. Pelikan, and E. Weinschenk. E. Richat observed the action of **N-rays.** J. Ewles studied the **cathode ray** luminescence of tin oxide. V. von Agafonoff said that cassiterite is transparent for **ultra-violet light** as far as the cadmium line. J. O. Perrine found no fluorescence in the ultra-violet rays. A. de Gramont found that all the tin lines show clearly in the **spark spectrum** of cassiterite. W. W. Coblentz found small absorption bands in the **ultra-red transmission spectrum** of cassiterite at

$1\cdot3\mu$, 3μ, $5\cdot8\mu$, $6\cdot6\mu$, $7\cdot3\mu$, $8\cdot25\mu$, $9\cdot7\mu$, and $10\cdot4\mu$. He also found that stannic oxide emits a continuous spectrum, with a small band at $3\cdot2\mu$. G. A. Dima studied the **photoelectric effect** with tin oxide. W. Crookes found that stannic oxide does not show an appreciable phosphorescence in **cathode rays.**

According to F. von Kobell,[12] cassiterite is a non-conductor of electricity; while F. Beijerinck, and G. Cesaro found that it is a conductor, and, according to the former, the **electrical conductivity** is less in the direction of the c-axis than it is perpendicular to that axis. J. Königsberger and O. Reichenheim, however, showed that transparent colourless cassiterite is a non-conductor, and that the dark-coloured crystals are conductors. G. Tammann and H. Bredmeier measured the conductivity of thin films of the oxide. C. Doelter measured the **electrical resistance** of a plate cut parallel to the c-axis, and found the sp. resistance, R ohms, to be on a rising temp. :

	360°	500°	700°	900°	1060°	1200°	1430°
R . . .	3550	1060	1050	29	5·0	1·2	0·85

and on a falling temp.,

	1270°	1200°	1080°	1010°	930°	780°
R . . .	0·980	1·105	1·488	1·6888	2·677	55·80

No polarization phenomena were observed, and it was inferred that the conductivity is not due to ionization. According to T. Liebisch, sections of cassiterite cut parallel to the basal plane and parallel to the principal axis of crystals of cassiterite show a well-marked zonal structure. The dark kernel of these crystals is strongly negative thermo-electrically with respect to copper, whilst the paler coloured shell is inactive. When placed between the electrodes of an electric wave detector the dark kernel reacts strongly, whilst the paler shell is inactive. For this reason crystals of cassiterite only act in the detector when the darker coloured pyramid faces, and not the paler prism faces, are in contact with the electrodes. B. Saklatwalla recommended stannic oxide as a resistance medium for electrical heating. K. Fischbeck studied the electrochemical reduction of cassiterite. W. Schmidt could not determine the **dielectric constant** of a crystal of cassiterite from Altenberg, on account of its great electrical conductivity. E. T. Wherry found that cassiterite showed no evidence of the rectification required by a radio-detector. According to V. von Lang, cassiterite is paramagnetic, and it is greater in the direction of the c-axis than it is perpendicular thereto. S. Meyer gave for the **magnetic susceptibility** $-0\cdot082 \times 10^{-6}$ units per gram, and $-0\cdot006 \times 10^{-6}$ per mol.

The chemical properties of stannic oxides.—W. A. Tilden[13] found that cassiterite from the Straits Settlements occludes 1·3 parts of gas, 45·4 per cent. of which is carbon dioxide. C. M. Despretz showed that stannic oxide is reduced when heated in a current of **hydrogen** at the temp. at which tin decomposes steam. W. Müller found the reduction begins at about 170°. W. Hampe, H. Haas, and A. E. Arnold employed this method for breaking down cassiterite to a state where the contained tin can be dissolved in acids and analyzed. L. Wöhler and O. Balz studied the reduction of stannic oxide, and the oxidation of stannous oxide (q.v.). J. C. S. Wells, and H. Mennicke showed that when stannic oxide is treated with a mixture of zinc and hydrochloric acid, the oxide is reduced to tin which dissolves in the acid. E. D. Clarke, and C. H. Pfaff observed the reduction of cassiterite in the oxy-hydrogen flame. Cassiterite or stannic oxide is very resistant towards chemical agents. The oxide is not affected when heated in **air** or **oxygen ;** nor has **water** any action. This is illustrated by the water-worn granules which occur as stream tin in alluvial deposits; it seems to survive indefinitely in detrital deposits. A. Kenngott observed no reaction when the moist powder is tested with litmus, but after it has been calcined in a reducing flame, it does show an alkaline reaction.

When heated in a current of **chlorine**, R. Weber found that stannic chloride is formed; and A. E. Arnold found that by heating cassiterite in a stream of **hydrogen chloride,** or digesting the mineral in conc. **hydrochloric acid** at 100°, most of the stannic oxide dissolves. The stannic oxide in a few rare minerals is also extracted by digestion with this acid. In general, however, aq. soln. of acids scarcely affect cassiterite or calcined stannic oxide. F. de Lalande and M. Prud'homme heated stannic oxide and an alkali chloride in a current of air, and they found that the reaction can be symbolized: $SnO_2 + 2NaCl + O = Na_2SnO_3 + Cl_2$. According to E. Stelling, if the oxide be digested in sulphurous acid, it afterwards dissolves readily in hot hydrochloric acid. Fused **potassium hydrofluoride** was found by W. Gibbs to dissolve stannic oxide. C. Matignon and F. Bourion found that when cassiterite is heated in chlorine charged with the vapour of **sulphur chloride,** SCl_2, stannic chloride is formed. R. Weber found that when stannic oxide and **sulphur** are heated together, stannic sulphide is formed; and, according to H. Rose, a molten mixture of sulphur and sodium carbonate transforms stannic oxide into sodium thiostannate. D. L. Hammick said stannic oxide remains unchanged by **sulphur dioxide** at a red heat; and E. Stelling also found that it is not reduced by sulphurous acid. H. Rose found that when a mixture of conc. **sulphuric acid** is heated, a syrupy liquid is formed from which water precipitates all the stannic oxide; and that molten **potassium hydrosulphate** dissolves stannic oxide, but when the cold mass is treated with water, the stannic oxide is precipitated completely.

P. Sabatier and J. B. Senderens showed that at temp. below 500° stannic oxide is not affected by **nitrous oxide, nitric oxide,** or **nitrogen peroxide.** C. T. Barfoed showed that **phosphorus trichloride** reacts with stannic oxide at 160°, forming a mixture of stannous and stannic chlorides. A. Michaelis also studied the reaction. D. B. Dott found that stannic oxide is reduced to tin by **hypophosphorous acid.** Stannic oxide is reduced to the metal when heated with **carbon ;** and, according to F. O. Döltz and C. A. Graumann, the reaction begins between 800° and 810°. R. E. Slade and G. I. Higson found that the equilibrium press. of the oxide with carbon is over 760 mm. at 750°. H. Moissan said that stannic oxide is reduced when heated with **calcium carbide,** forming the metal but not a tin carbide. F. von Kügelgen found that the reaction begins at a dull red heat, and that it proceeds smoothly at a bright red heat if calcium chloride be used as a flux. The tin retains about 0·4 per cent. of calcium. C. M. Despretz, and P. G. F. Leplay and A. Laurent observed the reduction of stannic oxide by **carbon monoxide.** According to I. L. Bell, the stannic oxide is not attacked at a dull red heat. F. Schlagdenhauffen and C. Pagel said that no reduction occurs below 300°; but K. Stammer said that at a higher temp. stannic oxide is first reduced to stannous oxide and then to tin. R. E. Slade and G. I. Higson found that equilibrium occurs at 750°, when stannic oxide and carbon are heated in a closed vessel and the press. is over 760 mm.; and at 753°, when the press. is 670° mm. T. Maeda found, at 700°–950°, the state of equilibrium: $SnO_2 + 2CO \rightleftharpoons Sn + 2CO_2$, where the equilibrium constant, K, is given by $\log K = -641\cdot8T^{-1} + 1\cdot084$; and the thermal value of the reaction $SnO_2 + 2CO = Sn + 2CO_2 - 5\cdot87$ Cals. at 80°. The kinetics of the reduction was also studied by W. Fränkel and K. Snipischsky; they gave 1·46 Cals. for the heat of the reaction; and found equilibrium was attained in a few weeks at 500°; in a few days at 600°; at 670°, in about $2\frac{1}{4}$ hrs.; and at 755°, in half an hour. The results at 670°, 720°, and 755° are illustrated in Fig. 64, where the lower
Fig. 64.—Equilibria in the Reaction $Sn + 2CO_2 \rightleftharpoons SnO_2 + 2CO$.

curves refer to the oxidation of tin by carbon dioxide, and the upper to the reduction of stannic oxide by carbon monoxide : $Sn+2CO_2 \rightleftharpoons SnO_2+2CO$.   For the constant $C_{CO_2}K=C_{CO}$:

	600°	700°	800°	900°	1000°	1100°	1200°
K . . .	0·28	0·27	0·25	0·22	0·13	0·07	0·05

S. Medsforth examined the effect of stannic oxide on the catalytic action of nickel in the reduction of carbon monoxide and dioxide by hydrogen. W. Müller said stannic oxide is not altered when heated in a current of **methane,** or **ethylene ;** but W. Ipatieff showed that the vap. of **alcohol** forms acetaldehyde and ethylene when passed through a tube packed with stannic oxide and heated to 650° ; metallic tin is formed. A. Mailhe said that ethyl alcohol vap. rapidly reduces stannic to stannous oxide at 340°, and the reduction of the stannous oxide to the metal proceeds rather slowly ; acetaldehyde and hydrogen are formed. According to J. von Liebig, stannic oxide is quickly reduced to the metal by molten **potassium cyanide.** According to L. Hackspill and R. Grandadam, while fused **alkali cyanides** reduce the oxide under ordinary atm. conditions to metal and alkali carbimide, yet, at 570°–750°, in vacuo, sodium cyanide yields eq. proportions of sodium and tin, along with nitrogen, carbon monoxide and dioxide, and carbon. Sodium carbimide is probably first formed, and it decomposes under the reduced press. J. Milbauer found that molten **potassium thiocyanate** reacts vigorously with stannic oxide, forming stannous sulphide and then potassium thiostannate. According to C. W. Watts and C. A. Bell, and C. Renz, **carbon tetrachloride** reacts with red-hot stannic oxide, forming stannic chloride. N. P. Peskoff found that the presence of colloidal stannic oxide facilitated the action of X-rays on organic compounds. G. Rauter found that **silicon tetrachloride** reacts between 350° and 360°, forming stannic chloride and silica. C. H. Burgess and A. Holt said that stannic oxide is quite insoluble in fused **boric oxide.** A. Lomax showed that the solubility of stannic oxide in fused **silicates** increases with the proportion of contained alkali. The insolubility of the oxide in fused silicates determines its utility as an opacifying agent in glasses, glazes, and enamels. The subject has been investigated by R. R. Danielson and M. K. Frehafer. K. B. Lehmann has examined the dissolution of tin oxide by hot acetic acid from enamels opacified with this oxide.

Stannic oxide is reduced to the metal by **potassium** or **sodium** at a gentle heat ; and the reaction is accompanied by incandescence. C. Winkler showed that the reduction of stannic oxide heated with **magnesium** occurs with explosive violence ; H. Goldschmidt reduced stannic oxide by heating it with **aluminium.** W. O. Snelling showed that cassiterite in contact with **zinc** and hydrochloric acid is reduced by cathodic action. According to A. E. Arnold, aq. soln. of the **alkali hydroxides** have very little action on cassiterite ; H. D. Rankin said that after heating to redness, stannic oxide dissolves in alkali-lye when the mixture is heated in an autoclave. H. Rose found that the oxide is completely dissolved by fused alkali hydroxides, while it is scarcely attacked by molten **alkali carbonates.**

§ 13. The Stannic Hydroxides ; and the Stannic and Perstannic Acids

In 1716, J. Kunckel studied the action of nitric acid on tin and showed that it can be dissolved only when a small proportion is added to the acid, and that heat must be avoided because the white tin calx is thrown down when the acid is hot. Robert Boyle [1] made several references to the action of nitric acid upon tin. He said that the acid eats up or destroys more tin than it dissolves ; and in his *Experiments and Observations upon Colours* (London, 1670), he said :

Tin, corroded by aqua fortis, till the menstruum will work no farther on it, becomes exceedingly white ; and easily, of itself, acquires the consistence not of a metalline calx, but of a coagulated matter, so like either to curdled milk, or curdled white of eggs, that a person unacquainted with such soln. might easily be mistaken in it.

These statements mean that with dil. nitric acid, tin forms stannous or stannic nitrate according to the conc. of the acid ; and that the salts readily decompose with the separation of gelatinous stannic acid. With conc. nitric acid, much heat is evolved, and a white insoluble powder, the so-called metastannic acid, is formed. In 1811, J. J. Berzelius showed that tin hydroxide prepared by the action of nitric acid on tin possesses properties which are not found in the hydroxide precipitated

from tin chloride by an alkali like ammonia. At that time, it was assumed that the two hydrates represented different stages of oxidation, but J. Davy, and J. L. Gay Lussac, and, later, J. J. Berzelius showed that this was not the case. Both hydroxides contain the same proportion of oxygen, but possess different properties; and J. J. Berzelius thus regarded them as isomeric modifications. The hydroxide obtained from stannic chloride contains $SnO_2.nH_2O$, which saturates three times as much base as the hydroxide obtained by the action of nitric acid on tin. He likened the latter to metaphosphoric acid, and called it *oxidum stannicum*, and the former to ordinary phosphoric acid, and called it *oxidum parastannicum ;* E. Frémy designated the latter *acide metastannique*, and the former *acide stannique*. J. J. Berzelius also called the acid derived from the action of nitric acid on tin, β-**stannic acid,** and that obtained by precipitation from a soln. of stannic chloride, α-**stannic acid.** Both acids dissolve in aq. soln. of alkali hydroxides or carbonates, and when reprecipitated by acids they retain the properties they had before they were dissolved in the alkali-lye. Either modification can be transformed into the other. J. J. Berzelius contrasted the more salient differences :

α-STANNIC ACID	β-STANNIC ACID
This acid is the more basic one and furnishes salts which are readily soluble in water without decomposition. The moist acid is easily soluble in nitric acid ; it is also soluble in dil. sulphuric acid, and the soln. does not gelatinize when boiled. It dissolves easily in hydrochloric acid, and when boiled the soln. remains clear.	This acid is the less basic one, and furnishes salts which are sparingly soluble in water, and are hydrolyzed into an insoluble basic salt and acid. The acid is insoluble in nitric acid ; and it is insoluble even in conc. sulphuric acid. It unites with hydrochloric acid, forming a substance insoluble in an excess of the acid, and soluble in water. The aq. soln. gelatinizes when boiled.

The cause of these differences has not been clearly established. Investigations are difficult because the characteristic properties are not very pronounced, and they readily change, one into the other, so that some contradictory reports are based on observations with mixtures of the two isomers, and not with homogeneous substances. Two types of hypotheses have been devised to explain the differences ; one set assumes that one of the alleged stannic acids is a colloidal form of the other ; and the other set assumes that, as J. J. Berzelius supposed, the one acid is an isomeric form of the other ; and, as E. Frémy assumed, that one acid is a polymeric form of the other.

1. *Polymerization or condensation hypotheses.*—It is here assumed that two distinct and definite substances are capable of existence, and that the one is a polymerized form of the other. E. Frémy first regarded the β-acid as a polymerized form of the α-acid. Using the prefixes with the same meaning as employed in dealing with the carbonic, silicic, tannic, and zirconic acids, the α-acid was assumed to be metastannic acid, H_2SnO_3, and the β-acid, a polymerized form. E. Frémy at first represented the β-acid by the formula $H_2Sn_3O_7.2H_2O$, or $H_6Sn_3O_9$, i.e. $(H_2SnO_3)_3$, but later adopted the formula $H_2Sn_5O_{11}.4H_2O$, or $H_{10}Sn_5O_{15}$, i.e. $(H_2SnO_3)_5$. This view was supported by H. Rose, H. Schiff, and C. T. Barfoed, but H. Rose gave for the formula $H_{14}Sn_7O_{21}$; H. Schiff, $H_{10}Sn_6O_{17}$; and C. T. Barfoed, $H_{18}Sn_9O_{27}$. F. Musculus concluded that there is a whole series of polymerized forms between H_2SnO_3 and E. Frémy's $(H_2SnO_3)_5$, but R. Weber said that the constancy of the composition of the alkali salts lends no support to this hypothesis. J. M. Ordway's products with $Na_2O : SnO_2=1 : 3$, $1 : 5$, $1 : 7$, etc., were probably so-called adsorption compounds. From his observations on the thermal value of the reaction between alkali-lye and various modifications of stannic acid, L. Vignon inferred that a whole series of stannic acids exists, the extremes being the acid completely soluble in water and ignited stannic oxide. The composition of metastannic acid indicates that condensation does not take place by elimination of water, but is the result of mol. rearrangement which

produces a gradual diminution of the activity of the acid function. The polymerization may be regarded as due to the energetic acid function of the simple acid, which unites with a number of its own mols. which play the part of a base. J. Biron also assumed that by condensation an uninterrupted series between α- and β-acids could be obtained. R. Lorenz compared the rates at which the α- and β-stannic acids are dehydrated under similar conditions, and inferred that their composition is identical, and that both exist in all stages of hydration between H_4SnO_4 and H_3SnO_3. The compounds retain their characteristic properties after repeated precipitation from salts or soln., and the salts are different. R. C. Engel suggested that the so-called intermediate acids are not homogeneous substances, but mixtures, α-stannic acid or orthostannic acid, β-stannic acid or metastannic acid, and a third acid which he called *parastannic acid*. He represented the composition of these acids, their potassium salts, and their chlorides,

TABLE VI.—THE COMPOSITION OF R. C. ENGEL'S STANNIC ACIDS.

Stannic acids.	Dried in air.	Dried at 100°.	Potassium salts.	Chlorides.
Ortho- .	$H_2SnO_3.H_2O$	H_2SnO_3	$K_2SnO_3Aq.$	$SnCl_4Aq.$
Meta- . .	$H_2Sn_5O_{11}.9H_2O$	$H_2Sn_5O_{11}.4H_2O$	$K_2Sn_5O_{11}.4H_2O$	$Sn_5O_9Cl_2.4H_2O$
Para- . .	$H_2Sn_5O_{11}.7H_2O$	$H_2Sn_5O_{11}.2H_2O$	$K_2Sn_5O_{11}.2H_2O$	$Sn_5O_9Cl_2.2H_2O$

by Table VI. The parastannic acid of R. C. Engel was made by boiling the ordinary β-acid, or metastannic acid with water. A. Kleinschmidt, however, showed that this product is nothing but ordinary β-stannic acid; and his examination of the stannic acids led him to conclude that both α- and β-stannic acids are colloidal substances capable of reversible transformation. The change from the α- to the β-acids occurs more readily than the reverse action. The behaviour of these compounds towards acids is in harmony with the assumption that α-stannic acid has the composition H_2SnO_3, that is, stannyl hydroxide, $O=Sn=(OH)_2$, and β-stannic acid, $(H_2SnO_3)_5$, or

$$
\begin{array}{c}
(OH)_2 \\
O . Sn . O \\
(OH)_2=Sn \qquad Sn=(OH)_2 \\
O \qquad O \\
(OH)_2=Sn . O . O.Sn=(OH)_2 \\
\text{β-stannic acid.}
\end{array}
$$
in which only two of the hydroxyl groups are replaced by Cl-, NO_3-, SO_4-, or (ONa)-radicles. This makes the formula $Sn_5O_5(OH)_8(OH)_2$. With the previously used nomenclature, α-stannic acid is **metastannic acid**, H_2SnO_3, or stannyl hydroxide, $SnO(OH)_2$; and β-stannic acid is **pentametastannic acid**, $(H_2SnO_3)_5$, or $H_{10}Sn_5O_{15}$, or **pentastannyl decahydroxide**, $(SnO)_5(OH)_{10}$. On the other hand, N. Yamada found no difference in the X-radiograms of the stannic acids prepared by different processes, and hence inferred that the difference is not due to chemical differences, but rather to the way the water adheres to the surface of the oxide granules. P. Pascal's observations on the magnetic susceptibilities of the stannic acids indicate that they are not definite compounds, but mixtures of stannic oxide and water; while R. Willstätter, H. Kraut, and W. Fremery's experiments on the dehydration indicates that definite hydrates are formed. Thus, stannic hydroxide gels prepared by the action of ammonia and ammonium chloride on stannic chloride under conditions which ensure a low hydroxyl-ion conc. and great rapidity of experiment, and subsequently dried by acetone at −35° to −10°, have the composition, $Sn(OH)_4.H_2O$, whereas after similar treatment at the atmospheric temp. they have the composition of the ortho compound, $Sn(OH)_4$. Monostannic acid becomes transformed in an aq. medium into a more feebly basic acid which appears

to be the first member of a series of α-stannic acids (previously designated α'-acids). When dried by the acetone process at 0°–10°, the product has approximately the composition of an orthodistannic acid, $(OH)_3Sn.O.Sn(OH)_3$, whereas after treatment at 30°–56° or prolonged heating with acetone, it has exactly the composition of an *orthotetrastannic acid*, $(OH)_3Sn.O.Sn(OH)_2.O.Sn(OH)_2.O.Sn(OH)_3$. The union of several mols. of stannic hydroxide with loss of water appears to yield a series of polyorthostannic acids with diminishing basic properties.

2. *Colloidal hypotheses.*—G. C. Wittstein assumed that the α-acid is amorphous, and the β-acid is crystalline; but this view is untenable, for, as just indicated, both stannic acids are colloidal. J. M. van Bemmelen investigated the dehydration and rehydration of the stannic acid gels, and failed to obtain any evidence of the existence of definite hydrates of stannic oxide, and he considered both the stannic acids to be colloids, and the β-stannates were considered to be " adsorption compounds." According to W. Mecklenburgh, *the difference in the behaviour of the different stannic acids is due to differences in the sizes of the particles ;* the modifications with the most highly developed β-characteristics were supposed to have the largest primary particles. R. Zsigmondy, and H. B. Weiser accepted this hypothesis, and R. R. Franz said that the primary particles are of amicronic dimensions, and that in sol-systems there is a gradual transition from the mol. to the primary particles and onwards, by complex formation, to secondary particles. W. Pauli also expressed the view that many sols of metallic compounds contain complex mols. due to the union of, for example, some of the simple mols. of the original substance with mols. formed by the hydrolysis of the original compound. The particular properties of a given stannic acid are thus assumed to be dependent on the grain-size, and that the grain-size is determined by the temp. of preparation, etc. A. Tian assumed that the coalescence of particles reducing the degree of dispersion is due to the operation of capillary forces; and G. E. Collins and J. K. Wood inferred that the difference in the character of α- and β-stannic acids depends on the extent to which a process of condensation between mols. of stannic hydroxide has taken place, the cause of this condensation being the amphoteric nature of the hydroxide. The first step in this process of condensation was considered to be the formation of α-stannic acid, H_2SnO_3, from a single mol. of stannic hydroxide; the gradual conversion of the α-acid into the β-modification, which takes place slowly at the ordinary temp. and more rapidly on boiling, is due to the continuation of the process of condensation, thus leading, by the loss of water from several mols., to the production of mols. of gradually increasing complexity and of increasing β-character; thus, $SnO(OH)_2$ with one mol. ; $(OH)_3Sn.O.Sn(OH)_3$ with two mols. ; and so on, even to A. Kleinschmidt's formula. This form of the colloidal hypothesis reinstates the polymerization or condensation hypotheses.

The preparation of α-stannic acid.—J. J. Berzelius made α-stannic acid by treating a soln. of stannic chloride with alkali hydroxide, and washing the precipitate ; if potassium carbonate is used as precipitant, a sparingly soluble stannate is formed. R. Lorenz used stannic bromide in place of the chloride. A. Ditte used alkali hydrocarbonate, and E. Frémy, and H. Schiff used calcium or barium carbonate as precipitant. E. Frémy treated alkali stannate with acid ; P. T. Austen passed carbon dioxide into the soln., or boiled it with a hydrocarbonate. H. Rose boiled a dil. aq. soln. of stannic chloride, but R. Engel found the precipitate so obtained is a mixture of α- and β-stannic acids. G. Neumann treated a soln. of stannic chloride and an excess of ammonium sulphate with a little hydrogen sulphide ; alkali sulphates, without hydrogen sulphide, precipitate α-stannic acid from the soln., but alkali chlorides or nitrates do not do so. R. Lorenz electrolyzed a soln. of alkali chloride, nitrate, or sulphate, using a platinum cathode, and a tin anode.

J. Löwenthal found that β-stannic acid is transformed into the α-acid by treatment with conc. hydrochloric acid ; and, added C. T. Barfoed, the transformation is proportional to the temp., the time, and the proportion of hydrochloric acid

employed. The hydrate dried above 100° is less easily transformed than that dried at a lower temp. H. Allen found that conc. sulphuric acid transforms β-stannic acid to stannic sulphate which, when treated with cold water, precipitates the α-acid. L. Vignon boiled for 4 hrs. a mol of the β-acid with 20 mols of potassium chloride and as much water, and obtained the α-acid. A. Moberg, and H. Rose melted the β-acid with potassium hydroxide, or boiled an alkaline soln. of the alkali stannate, and E. Frémy found that potassium β-stannate in contact with a conc. soln. of potassium hydroxide gives a precipitate of the α-acid in a few days at ordinary temp. A soln. of **colloidal α-stannic acid** is produced by the method used for silicic acid. T. Graham dialyzed a soln. of stannic chloride mixed with alkali-lye, or a soln. of potassium stannate mixed with hydrochloric acid.

In both cases a gelatinous mass forms on the dialyzer, but as the salts diffuse away, the jelly is again peptized by the small proportion of free alkali remaining. The alkali itself may be removed by continued diffusion, a drop or two of the tincture of iodine facilitating the separation. The liquid α-stannic acid is converted, on heating, into liquid β-stannic acid. Both liquid acids are remarkable for the facility with which they are peptized by a minute addition of hydrochloric acid, as well as by salts.

T. Graham also dialyzed a soln. of freshly precipitated gelatinous stannic acid in one of stannic chloride and obtained stannic hydroxide as a gelatinous mass. Whatever the conc. of the soln. submitted to dialysis, the product was always the same, viz., α-stannic acid. E. A. Schneider poured a dil. soln. of stannic chloride into dil. aq. ammonia until the precipitate dissolved ; more water was added, and the soln. dialyzed. The product is transformed by dil. acids, other than nitric acid, into a hydrogel ; conc. sulphuric or hydrochloric acid forms the corresponding salt. The hydrosol and stannous chloride produce a yellow liquid, probably colloidal tin sesquioxide : $SnO_2 + SnCl_2 + H_2O = 2HCl + Sn_2O_3$. J. M. van Bemmelen made colloidal stannic acid by dialyzing hydrochloric acid or alkaline soln. of stannic acid ; by the action of calcium carbonate on an aq. soln. of the chloride ; by the action of carbon dioxide or air on a soln. of an alkali stannate. W. Biltz dialyzed the filtered soln., obtained by mixing eq. proportions of stannic chloride and lead nitrate in dil. aq. soln. The product was contaminated with lead nitrate. R. Zsigmondy made stannic acid by dissolving 3 grms. of tin in hydrochloric acid, and the soln. of stannous chloride diluted with 4 litres of water ; air was passed through the liquid for 5 days, and the gelatinous precipitate washed by decantation. The product is not soluble in conc. acids, but it is soluble in dil. hydrochloric, sulphuric, or nitric acid ; dil. potash-lye dissolves the colloid more readily than does soda-lye, and the α-stannic acid passes into the β-form. W. A. Patrick made hydrogels by the action of acids on a soln. of stannic chloride. According to J. Bellucci and N. Parravano, when a soln. of potassium stannate, cooled with ice, is treated with a small proportion of hydrochloric acid, the precipitate, after being washed repeatedly with cold water, has the same composition—$H_2SnO_3.H_2O$, or $Sn(OH)_4$, **stannic hydroxide,** or **orthostannic acid**—after 6 days' drying in air as it has after 30 days' similar drying.

The properties of α-stannic acid.—As J. J. Berzelius, E. Frémy, and others have shown, α-stannic acid is a white, voluminous, amorphous or colloidal precipitate which when dried looks like bits of glass. The moist product reddens blue litmus, and is dissolved or rather peptized by water. J. Thomsen gave for the heat of formation $(Sn, O_2, 2H_2O) = 133\cdot49$ Cals., and for the heat of neutralization, with hydrochloric acid, $(H_4SnO_4, 4HCl) = 3\cdot11$ Cals. ; and with sodium hydroxide, $(H_4SnO_4, 4NaOH) = 9\cdot56$ Cals. L. Vignon found for $(H_2SnO_3, 4KOH)$ numbers varying from 21·3 to 32·7 Cals. dependent on the mode of preparation. According to R. C. Engel, there is a tendency for the α-acid on drying to pass into the β-acid, so that the product is a mixture of both acids. When dried rapidly in air, R. Engel's α-acid had 32·7 per cent. of water ; and the air-dried α-acid was found by E. Frémy to contain 22·5 per cent. of water, and by R. Weber, 22·73 per cent. When dried over conc. sulphuric acid, E. Frémy found the α-acid contained 11·2 per cent.

of water; R. Weber, 12·45 per cent.; and R. Lorenz, 12·6 per cent. T. Graham, R. C. Engel, and L. Schaffner found that when dried at 100°, the composition corresponded with H_2SnO_3. R. Lorenz found that when dried at 130°, 7·5–7·6 per cent. of water was present; and when dried at 140°, 7·4 per cent. After drying at 170°, H. Rose said that it no longer loses weight when heated, but J. B. A. Dumas said that a red heat is necessary to drive off all the water. T. Carnelley and J. Walker observed no signs of the formation of a definite hydrate in their observations on the drying of α-stannic acid at different temp. According to C. T. Barfoed, the hydrate dried at 100° gradually absorbs moisture from the air, and, according to J. M. van Bemmelen, a mol of stannic acid in a moist atm. absorbs 2·7–3·0 mols of water, and when dried over sulphuric acid, 2–2·3 mols are lost; at 100°, 1·7–1·8 mols; and at a red heat, 0·8 mol. He also found that a sample with $1·07H_2O$ after drying many days in dry air at ordinary temp., contained:

95° (¼ hr.)	105° (1¼ hrs.)	110° (4 hrs.)	120° (3 hrs.)	145° (3 hrs.)	165° (4 hrs.)
$0·99H_2O$	$0·88H_2O$	$0·74H_2O$	$0·72H_2O$	$0·60H_2O$	$0·56H_2O$

S. Glixelli studied the electro-osmosis of stannic acid. Freshly precipitated α-stannic acid readily dissolves in mineral acids. According to J. Bellucci and N. Parravano, the soln. in nitric acid gradually gelatinizes on standing, and becomes clear again when ammonium nitrate is added. The soln. in nitric acid coagulates at 50°; the soln. in sulphuric acid is stable; and the soln. in hydrochloric acid is not precipitated by an excess of hydrogen chloride. H. Kühl found that the stannic acid obtained by treating a hot soln. of sodium stannate with sulphuric acid, when freshly prepared, is completely soluble in 5 per cent. hydrochloric acid and conc. sulphuric acid; the soln. in the latter deposits prismatic crystals when heated. The stannic acid, kept as a paste for ten days, is soluble in 5 per cent. hydrochloric acid only on boiling, and is only partly soluble in conc. sulphuric acid; the insoluble gelatinous portion is not completely soluble in conc. hydrochloric acid, neither is the gelatinous stannic acid precipitated on heating the sulphuric acid soln. The stannic acid, obtained by carefully adding dil. sulphuric acid to a cold soln. of sodium stannate when freshly prepared, is readily soluble in 2 per cent. hydrochloric acid and conc. sulphuric acid; the soln. in sulphuric acid gives no deposit when heated. The acid loses its solubility in sulphuric acid, but not in hydrochloric acid, when kept for some time in a pasty condition. The stannic acid, obtained from a freshly prepared soln. of sodium stannate, is readily soluble in 2 per cent. hydrochloric acid and 2 per cent. potassium hydroxide, whereas that obtained from the same soln. after being kept for 12 days is not soluble in soln. containing less than 6 per cent. of potassium hydroxide and 5 per cent. of hydrogen chloride. F. Hein and H. Meininger observed that stannous hydroxide is a feeble base, but when all the hydroxyl radicles except one are replaced by ethyl or phenyl radicles, strong bases are formed. J. Bellucci and N. Parravano showed the α-acid is soluble in or peptized by soln. of alkali hydroxides, and the soln. does not give a precipitate when treated with an excess of the alkali-lye. The α-acid is also dissolved by soln. of alkali carbonates, and ammonia. The soln. in alkali-lye furnish salts in which the α-characteristics persist, and in the salts α-stannic acid behaves as if it were dibasic $K_2SnO_3.3H_2O$. The water is expelled only at a high temp., and the salts are isomorphous with *potassium hexahydroxy-platinate*, and hence it was suggested that the α-stannates are salts of an unknown dibasic *hydrohexahydroxystannic acid*, $H_2[Sn(OH)_6]$. W. Herz found that stannic hydroxide, $Sn(OH)_4$, diffuses in alkaline soln. like stannous hydroxide, $Sn(OH)_2$. According to A. Moberg, and H. Rose, the α-stannates are obtained by heating the β-stannates with an excess of alkali-lye. W. Biltz and F. Zimmermann observed no coloration when the freshly precipitated hydroxide is treated with $0·1N$-silver nitrate; nor did J. Löwenthal observe any such coloration with α-stannic acid and stannous chloride as occurs with β-stannic acid. Colour reactions with phenols were indicated by L. Vignon, and L. Levy. A. M. Morley and J. K. Wood found

that like titanic acid, α-stannic acid precipitated from alkaline soln. absorbs basic dyes, and α-stannic acid precipitated from slightly acid soln. adsorbs acid dyes. G. E. Collins and J. K. Wood measured the isotherms of the adsorption by different forms of stannic acid, and found that more tin than chlorine is taken up by the colloidal acid. The adsorptive power does not depend wholly on size of grain, and it is less in the presence of hydrochloric acid. H. B. Weiser studied the precipitation of sols of α-stannic acid by electrolytes; and R. Schwarz and H. Stock, the coagulation of silver bromide emulsion by α-stannic acid. H. Zocher showed that the low crystallization velocity of stannic oxide, resulting from its slight solubility, facilitates its assumption of the colloidal state. The " ageing " of the colloid is accelerated or retarded by various influences, particularly by accompanying salts in soln. Coagulation, that is, the coalescence of the bounding surfaces of the colloidal particles in soln., is retarded by the electrostatic charge on the particles. A. Stiegler studied the gradual change in the electrical conductivity of colloidal stannic acid after peptization with an alkali, and he attributed the increase to the gradual break-down of stannyl stannate complexes, especially in dil. soln.

P. Pfeiffer and R. Lehnardt, and J. G. F. Druce have prepared *methyl stannonic acid*, $CH_3.SnO.OH$; *potassium methyl stannonate*, $CH_3.SnO.OK$; and *dimethyl stannone*, $(CH_3)_2SnO$. H. Lambourne represents the constitution of methyl stannonic acid as

$$\frac{CH_3}{HO}\!\!>\!\!Sn\!\!<\!\!\frac{O.Sn(CH_3)(OH)}{O.Sn(CH_3)(OH)}\!\!>\!\!O$$
J. G. F. Druce also made *ethyl stannonic acid*, $C_2H_5.SnO.OH$; *ethyl stannone*, $(C_2H_5)_2SnO$; *isopropyl stannonic acid*, $C_3H_7.SnO.OH$; *diisopropyl stannone*, $(C_3H_7)_2SnO$; and normal *propyl stannonic acid*, $C_3H_7.SnO.OH$; their potassium salts; and *dipropyl stannone*, $(C_3H_7)_2SnO$. He also made *sodium isopropyl stannonate*, as well as basic salts of calcium, barium, and strontium; and basic ethyl stannonates of silver, zinc, mercury, cobalt, nickel, and manganese.

The preparation of β-stannic acid.—The observations of C. T. Barfoed, E. Frémy, T. Graham, and J. Löwenthal show that α-stannic acid has a strong tendency to pass into the β-acid. This transformation sets in during the drying of the α-acid at ordinary temp., and also when it stands under water for some time. The change is faster when the liquid is warmed. H. Rose obtained the β-acid by boiling a soln. of stannic chloride with nitric acid until the hydrochloric acid is almost all expelled; and by allowing a soln. of stannic chloride to stand for a couple of years; by boiling a soln. of stannic chloride for a long time with an excess of conc. hydrochloric acid; and by allowing a soln. of stannous chloride in potassium hydroxide to stand exposed to the air—the β-stannic acid is precipitated gradually as the alkali hydroxide passes into carbonate. According to J. Löwenthal, and R. Lorenz, dil. soln. of stannic chloride form β-stannic acid more rapidly than conc. soln.; the transformation is hastened by potassium ferrocyanide, and retarded by tartaric acid. J. J. Berzelius prepared β-stannic acid by completely oxidizing tin with moderately conc. nitric acid, and washing the white powder with water until the wash-liquor no longer reddens blue litmus. D. B. Dott obtained the acid in a similar manner. According to R. Engel, the nature of the product of the action of nitric acid on tin depends on the conditions under which it is formed. If nitric acid of sp. gr. 1·42 is diluted with different proportions of water, kept at 0°, and a stick of tin immersed in 200 c.c. of the liquid, the products are (a) with 1 vol. of nitric acid and 2 vols. or more of water, stannous nitrate; (b) with equal vols. of water and acid, stannic nitrate, the liquid finally becoming syrupy; and (c) with undiluted acid, stannic nitrate, which, however, is precipitated, because it is insoluble in moderately conc. nitric acid. Stannic nitrate is, however, readily decomposed by water or by a rise of temp., the first product being stannic acid mixed with a small proportion of β-stannic acid, the proportion of the latter increasing, however, if the substance remains in contact with water, or if it is dried. The limiting compound in the cold is metastannyl stannate. When metastannyl stannate is boiled with water, the conversion into β-stannic acid proceeds further,

and parastannic acid is also formed in gradually increasing quantity. Pure meta-stannic acid yields parastannic acid when boiled with water; the latter may perhaps be regarded as an internal anhydride of the former. β-stannic acid is not formed by the direct action of nitric acid on tin; the substance described by J. J. Berzelius was in reality parastannic acid. G. Jörgensen recommended wash-ing the precipitate with conc. hydrochloric acid and showed that a large proportion of water is required to wash the product free from nitric acid. H. Rose showed that if the tin is alloyed with more feebly basic metals—e.g. bismuth—the β-stannic acid which is formed will be contaminated with considerable proportions of the oxides of these metals. If iron be present, the precipitated β-stannic acid contains iron and some iron and tin remain in soln. C. Lepéz and L. Storch, and F. H. van Leent studied the action of nitric acid on stanniferous alloys with the object of separating the tin as insoluble β-stannic acid for analytical purposes. Chromium behaves like iron; only a trace of tin passes into soln. if cerium is present, and none in the presence of aluminium, cobalt, nickel, copper, and uranium. J. Hood and A. G. Salmon obtained β-stannic acid by heating tin with a mixture of sulphuric acid and sodium nitrate. E. Frémy, and H. Rose prepared β-stannic acid by treating potassium β-stannate with acid; and R. Engel hydrolyzed sodium β-stannate, or metastannyl chloride by digestion in water at 60°. T. Graham obtained **colloidal β-stannic acid** by hydrolysis as in the case of the α-acid; and also by boiling a colloidal soln. of the α-acid. The aq. soln. of the product obtained by treating β-stannic with a little hydrochloric acid when dialyzed leaves a semi-transparent gelatinous mass of β-stannic acid. T. Graham added that there appears to be no soluble form of either α- or β-stannic acid, although they are colloidal substances. A. Dumansky and co-workers studied the formation of complexes as an intermediate stage in the synthesis of colloids.

The properties of β-stannic acid.—According to J. J. Berzelius, the product of the action of nitric acid on tin is a white, amorphous powder of sp. gr. 4·933; whilst that precipitated from α-stannates is gelatinous. The moist product reddens blue litmus, even though when calcined, water free from nitric acid is alone given off; but C. T. Barfoed always found some nitric acid was retained by the washed precipi-tate. L. Vignon found the heat of neutralization with air-dried β-stannic acid, $(H_2Sn_5O_{11}.9H_2O,2KOH)=11.5$ Cals.; that dried at 100°, $(H_2Sn_5O_{11}.4H_2O,2KOH)$ $=10.8$ Cals.; and that which has been heated to 250°, 5·3 Cals. R. Weber found the air-dried acid contained 21·3 per cent. of water; E. Frémy, that dried in air, 19·5 per cent.; and T. Thomson, that dried at 55°, 19˙36 per cent.; when dried over sulphuric acid, or in vacuo, R. Weber, and E. Frémy found 11·3 per cent. water—nearly $SnO(OH)_2$. When dried at 100°, L. Schaffner found 8 per cent.; at 930°, E. Frémy, 8·75 per cent., and R. Lorenz, 8·6 per cent.; at 140°, E. Frémy, 7·9 per cent.; and at 150°, L. Schaffner, 5·2 per cent. T. Carnelley and J. Walker observed no signs of the formation of a definite hydrate in their experiments on the dehydration of β-stannic acid at different temp. According to J. M. van Bemmelen, a mol. of β-stannic acid absorbs from moist air 2˙3 mols. of water; when dried over sulphuric acid, 1·07 mols.; when dried at 100°, 1·5 mols.; and at red heat, 0·65 mol. A sample with nearly a mol of H_2O after drying several days in a dry atm. at 15°, contained:

100° (1 hr.)	145° (5 hrs.)	165°	175° (4 hrs.)	185° (4 hrs.)
$0.68H_2O$	$0.60H_2O$	$0.56H_2O$	$0.53H_2O$	$0.487H_2O$

According to J. J. Berzelius, β-stannic acid is sparingly soluble in acids, and insoluble in nitric acid; it takes up a small proportion of some acids—e.g. sulphuric or hydrochloric acid—and when washed with a large proportion of water, the acid is removed; the product obtained with hydrochloric acid is soluble in water, and is precipitated from the soln. by acids. H. Rose added that the soln. obtained by using the smallest possible proportion of hydrochloric acid gives a precipitate when more of that acid is added. F. P. Treadwell represented the reaction with hydro-

chloric acid by the equations : $Sn_5O_5(OH)_{10}+10HCl=10H_2O+Sn_5O_5Cl_{10}$, when the product is insoluble in water : $Sn_5O_5Cl_{10}+8H_2O\rightleftharpoons 8HCl+Sn_5O_5Cl_2(OH)_8$, where the product is soluble in water ; and $Sn_5O_5Cl_2(OH)_8+2HCl\rightleftharpoons 2H_2O$ $+Sn_5O_5Cl_4(OH)_6$, where the product is insoluble in water. When the aq. soln. is boiled, hydrolysis is complete : $Sn_5O_5Cl_2(OH)_8+2H_2O=Sn_5O_5(OH)_{10}+2HCl$. According to J. J. Berzelius, the β-acid is less basic than the α-acid, and dil. alkali-lye dissolves β-stannic acid, forming β-stannates $M'_2Sn_5O_{11}.4H_2O$, which do not readily crystallize ; and excess of alkali-lye reprecipitates β-stannic acid. The β-acid is not dissolved by aq. soln. of ammonia or the alkali carbonates.

G. Varga, and J. N. Mukherjee studied the peptization of stannic acid by alkalies. R. Wintgren calculated from the transport numbers and electrical conductivities the proportion due to the micellar portion of the sol. In agreement with G. Varga, a measurable portion of the alkali is enclosed in the micellæ. J. M. van Bemmelen and E. A. Klobbie found that β-stannic acid has a very considerable power of absorbing hydrogen chloride from aq. soln. ; when equilibrium has been established, the conc. of the hydrogen chloride in the colloid is often greater than that in the aq. soln. The absorption factor k=(conc. in colloid)/(conc. in soln.) is not constant, but is dependent on the conc. at the point of equilibrium. β-stannic acid has an appreciable power of adsorbing potassium sulphate. From soln. of potassium chloride and potassium nitrate, the same colloid absorbs as much salt as makes the conc. in the colloid and in the soln. approximately equal. C. Lepéz and L. Storch found that when an acid soln. of ferric sulphate is mixed with β-stannic acid, no tin passes into soln. ; but if a mixture of β-stannic acid, ferric sulphate, and sulphuric acid be heated, and, when cold, poured into cold water, some tin remains in soln., but not if the cold mixture were to be poured into hot water. J. Löwenthal found β-stannic acid acquires a yellow colour in contact with a soln. of stannous chloride. H. Kreis showed that ferric hydroxide acts as a protective colloid on the peptized stannic acid. A mixture of the hydrated oxides of iron and tin in certain proportions is soluble in dil. ammonia. H. B. Weiser explained this by showing that hydrated stannic oxide is peptized by hydroxyl ion whilst hydrated ferric oxide is not. However, colloidal stannic oxide adsorbs ferric oxide and carries it into colloidal soln. as long as tin is present in excess. At the same time, hydrated ferric oxide adsorbs stannic oxide and tends to take it out of colloidal soln., so that when the former is present in large excess none of the latter remains peptized. Again, stannic oxide does not precipitate in the usual way from a soln. of tin in nitric acid containing a suitable amount of iron. H. B. Weiser explained this by showing that stannic oxide peptized by nitric acid coagulates spontaneously since the aged oxide is neither peptized nor dissolved by this acid. Ferric nitrate peptizes the oxide when newly formed and when aged. Accordingly, if freshly prepared stannic oxide is peptized either by ferric nitrate or by a suitable mixture of ferric nitrate and nitric acid, coagulation does not take place on standing or boiling on account of the stabilizing action of the strongly adsorbed ferric ion ; but if the concentration of ferric ion in the nitric acid soln. is too low, complete or partial coagulation takes place on standing or boiling. S. Ghosh and N. R. Dhar found soln. with 2·71 grms. of stannic oxide per litre were coagulated by electrolytes in accord. with Hardy's rule—3. 23, 8. The precipitating conc. being $0.1167N$-K_2SO_4 ; $0.1083N$-KCl ; $0.0020N$-$MgCl_2$; $0.0012N$-$BaCl_2$; $0.0012N$-$Th(NO_3)_4$; and $0.0009N$-$Al_2(CO_4)_3$. R. Wintgen, and J. Löwenthal investigated the mutual precipitation of tin oxide and chromic oxide gels, and found maximum precipitation occurred on mixing equi-normal conc. of the two soln. T. R. Briggs and W. J. Bartlett studied the adsorption of arsenious acid by metastannic acid. R. Weinland and M. Maier prepared complex salts with pyrogallol and pyrocatechol.

The perstannic acids and perstannates.—According to W. Spring,[2] when hydrated barium dioxide is added in excess to a hydrochloric acid soln. of stannous chloride, and the turbid liquid thus produced is dialyzed until barium chloride no longer passes through the membrane, the colloid residue, after evaporation

on the water-bath, yields a white mass whose formula is $H_2Sn_2O_7$, **perdistannic acid**, which may be regarded as the derivative of **stannic trioxide**, SnO_3, resulting from the following reactions : $SnCl_2+BaO_2=SnOCl_2+BaO$; $SnOCl_2 +BaO_2=SnO_3+BaCl_2$. When stannous acid precipitated from a soln. of stannous chloride by sodium carbonate was triturated with an excess of 30 per cent. hydrogen dioxide, and the mixture heated to 70°, S. Tanatar found that the product after drying for some days in a desiccator gave white, pulverulent **permonostannic acid**, $HSnO_4.3H_2O$. When this product was further dried in a desiccator, it slowly lost water and oxygen ; it also undergoes partial decomposition in water, forming stannic acid and hydrogen dioxide. When dried at 100°, its composition is trihydrated perdistannic acid, $H_2Sn_2O_7.3H_2O$. S. Tanatar also prepared **potassium permonostannate**, $KSnO_4.2H_2O$, by the action of hydrogen dioxide on potassium stannate; it is a white, amorphous powder, which, when heated, paŕts with oxygen and water. Its aq. soln. has an alkaline reaction ; on the addition of sulphuric acid, it decolorizes permanganate. When heated, it is converted into **potassium perdistannate**, $K_2Sn_2O_7.3H_2O$. **Sodium permonostannate**, $NaSnO_4.2H_2O$, was prepared in a similar manner, and is sparingly soluble in water, by which it is readily decomposed ; it is a white, amorphous powder. S. Tanatar said that a soln. of potassium permonostannate gives with platinic salt soln. a precipitate which is a mixture of platinic hydroxide and *platinic perstannate*.

According to A. Coppadoro, when conc. alkali stannate soln. are electrolyzed at low temp. and with low current densities, perstannates are formed, owing to anodic oxidation. The proportion of perstannate formed is only small, a condition of equilibrium being soon reached between the perstannate formed and decomposed. The addition of alkali fluoride to the electrolyte increases the rate of formation of the perstannate, but does not change the final equilibrium, so that the yield of perstannate remains unaltered. The presence of fluorine-ions does not increase the anodic potential during electrolysis, and it appears to form either a stable fluorine persalt or an intermediate compound which favours the oxidation of the stannate. The fact that perstannates are formed even at low current densities shows that their formation is due to secondary oxidation of the stannate by the nascent oxygen rather than by the union of two stannic anions. The yield of perstannate diminishes rapidly as the temp. of electrolysis rises. In soln. at the ordinary temp., the perstannates undergo gradual decomposition, yielding stannates.

§ 14. The Stannates

H. Rose[1] obtained what he regarded as **potassium α-stannate,** $K_2SnO_3.3H_2O$, or according to J. Bellucci and N. Parravano, $K_2Sn(OH)_6$, by fusing stannic oxide or one of its hydrates with potassium hydroxide or carbonate. If the fusion with potassium carbonate be interrupted before the carbon dioxide is all expelled, the gas still evolved from the interior of the cooling mass forces its way through the hardening crust with a crackling noise, and makes the surface uneven. J. C. G. de Marignac dissolved the cold soln. of stannic oxide in molten potassium hydroxide in water, and evaporated the soln. to allow the stannate, which is only sparingly soluble in a conc. soln. of potassium hydroxide, to crystallize. J. M. Ordway ignited a mixture of tin, potassium nitrate, and hydroxide ; dissolved the cold cake in water ; added an equal vol. of alcohol, of sp. gr. 0·84 ; purified the syrupy liquid by repeated soln. in water and reprecipitation with alcohol ; and finally evaporated the liquid in vacuo. E. Frémy dissolved α- or β-stannic acid in hot conc. potash-lye, and treated the soln. as just indicated. A. Moberg, and A. Ditte dissolved the stannic oxide or hydrate in hot conc. potash-lye and evaporated the sat. soln. over conc. sulphuric acid. J. Bellucci and N. Parravano washed the stannate rapidly with a little cold water ; then with alcohol ; and dried the product at 100°. They obtained it by adding an excess of potassium hydroxide to a soln. of stannic chloride or hydrochlorostannic acid. G. E. Collins and J. K. Wood recommended the following process :

Thirty grams of α-stannic acid prepared by the action of calcium carbonate on a soln. of stannic chloride was washed and dried in air. The product was fused with 80 grms. of potassium hydroxide, and the cold mass extracted with hot water and filtered. The

filtered soln. was evaporated until sat., and placed in vacuo over sulphuric acid as recommended by F. Musculus; the acid being subsequently replaced by sodium hydroxide. The small, clear crystals obtained were filtered off, rapidly washed once with distilled water, then several times with alcohol; and finally with ether.

H. Zocher prepared the *trihydrate*, $K_2Sn(OH)_6$; *tetrahydrate*, $K_2Sn(OH)_6.H_2O$; and the *pentahydrate*, $K_2Sn(OH)_6.2H_2O$. The potassium salts are more soluble than the sodium and lithium salts (*q.v.*). According to the analyses of A. Moberg, J. C. G. de Marignac, and J. Bellucci and N. Parravano, the composition agrees with $K_2SnO_3.3H_2O$, but E. Frémy considered the composition to be $K_2SnO_3.4H_2O$. The colourless, shining, oblique, rhombic prisms often have the acute lateral edges truncated. According to J. Bellucci and N. Parravano, the crystals belong to the trigonal system, and have the axial ratio $a : c = 1 : 1.9588$. The crystals are often twinned about the (100)-plane; and the cleavage parallel to (111) is perfect. The crystals are isomorphous with potassium hydroxyplatinate, $K_2Pt(OH)_6$. The birefringence is positive. F. Zambonini made observations on this subject. J. M. Ordway found the sp. gr. to be 3·197. According to J. L. Proust, the crystals turn red when heated, but they do not fuse. J. Bellucci and N. Parravano said that the crystals at 100° lose only traces of water, but at 140° water is copiously evolved. When the dehydrated stannate is heated, it no longer forms the original α-stannate when treated with water. They infer that the contained water is not present as water of crystallization, but, as indicated above, the water is an intrinsic part of the mol. The dehydrated salt is hygroscopic, and takes up water with the evolution of heat. The stannate appears to decompose into tin oxide and alkali on dehydration. According to A. Moberg, the salt does not deliquesce in air, and it is readily soluble in hot or cold water. J. M. Ordway found that 100 parts of water dissolve 106·7 parts of salt at 10°, and the sp. gr. of the soln. is 1·628; at 20°, 110·5 parts of salt are dissolved, and the sp. gr. of the soln. is 1·627. J. Bellucci and N. Parravano gave for the electrical conductivity, λ, of soln. containing half a mol of the salt in v litres of water at 25°:

v	32	64	128	256	512	1024
λ	97·5	105·6	113·2	122·8	134·9	155·8

and for the first two soln. the conductivity increases with time:

Time in hours	24	72	120	168
λ $\{v=32$	108·0	114·0	119·5	119·7
$\{v=64$	115·8	130·5	136·5	136·4

G. E. Collins and J. K. Wood found the velocity constant of the reaction $K_2Sn(OH)_6 + 2H_2O = H_2Sn(OH)_6 + 2KOH$ to be $k = 0.0188$, and the amount of free alkali present in a $0.128N$-soln. corresponds with a 13 per cent. hydrolysis. With a similar soln. of stannic chloride the hydrolysis was 94 per cent. This shows that stannic hydroxide is stronger as an acid than as a base. E. Frémy found that the aq. soln. gives a precipitate with soluble salts; and acids added to the soln. precipitate α-stannic acid soluble in nitric acid; J. M. Ordway showed that with dil. acids about one-fourth of the potash is precipitated, and that which remains in soln. is precipitated by alcohol as acid stannate which dries to a gummy mass. P. T. Austen made stannic oxide by passing carbon dioxide into an aq. soln. of an alkali stannate containing an excess of alkali; and, according to A. Ditte, when some bubbles of carbonic anhydride are allowed to fall on the surface of a dil. soln. of an alkali stannate, a cloudy separation of gelatinous stannic oxide rises to the surface, and, as it increases in amount, the carbon dioxide ceases to be absorbed. When, however, the carbon dioxide is introduced very slowly in contact with crystals of stannate, a dense monohydrated stannic oxide is formed, which seems to be amorphous. If carbon dioxide is passed into a mixture of stannate and carbonate, stannic oxide falls to the bottom of the liquid. Alkali carbonate free from the acid salt does not give rise to the production of stannic oxide when added

to a stannate; stannic oxide is formed in amount proportional to the quantity of acid salt present. N. W. Fischer found that if lead be immersed in the aq. soln., all the tin is precipitated; and R. Böttger, that copper in contact with tin is quickly plated with tin by the soln.

When an aq. soln. of this salt is treated with alcohol, J. J. Berzelius said that an acid salt is precipitated, while J. M. Ordway obtained the normal salt under this condition, J. J. Berzelius added that when a soln. of a salt is treated with potassium carbonate, hydrated stannic oxide is precipitated, and this, after the saline soln. has been removed by decantation, dissolves in water, forming a turbid liquid which gives a precipitate with potassium carbonate. R. Weber made an acid salt approximating $K_2O.5SnO_2$ by evaporating over sulphuric acid a soln. of potassium stannate sat. with stannic hydroxide; and, as indicated above, J. M. Ordway also obtained an acid stannate which varied in composition between $K_2O : SnO_2 = 1 : 5$ and $1 : 7$. These products appear to be mixtures of stannic acid with more or less adsorbed alkali, or alkali stannate.

A. Moberg prepared **sodium α-stannate**, $Na_2SnO_3.3H_2O$, or, according to J. Bellucci and N. Parravano, and H. Zocher, $Na_2Sn(OH)_6$, by saturating a soln. of sodium hydroxide with stannic hydroxide, and evaporating the soln. for crystallization. E. Frémy fused stannic acid with sodium hydroxide, dissolved the product in water, boiled the soln., and the sparingly soluble salt which was deposited was purified by recrystallization. R. Lüpke roasted cassiterite, and fused 6 grms. of the powdered product with 4 grms. of sodium hydroxide for 15 mins. in an electric furnace; the sodium stannate can be isolated as before. J. M. Ordway purified commercial sodium stannate by adding barium acetate to the soln., and treating the filtered soln. with alcohol. The salt is used in calico-printing under the name *preparing salts*. Technical processes have been described by R. E. Brown, E. Schunck, E. Haeffely, P. A. Bolley, T. Roberts and J. Dale, etc. Analyses by A. Moberg, J. C. G. Marignac, J. M. Ordway, R. F. Weinland and A. Gutmann, and J. Bellucci and N. Parravano gave $Na_2SnO_3.3H_2O$; while E. Frémy, and W. Prandtl gave $Na_2SnO_3.4H_2O$. H. Zocher said that while the trihydrate is formed at ordinary temp., the *tetrahydrate*, $Na_2Sn(OH)_6.H_2O$, is formed at 0°, or by alcohol at 0° or ordinary temp. A. Scheurer-Kestner said that at a low temp. a conc. soln. of sodium stannate, free from alkali hydroxide, furnishes long, prismatic crystals of the *decahydrate*, $Na_2SnO_3.10H_2O$; while E. Haeffely reported an *octohydrate*; and H. Jonas, an *enneahydrate*. The two latter are probably partly effloresced specimens of the decahydrate. The crystals, said A. Moberg, form six-sided tablets belonging, according to J. C. G. de Marignac, to the trigonal system and have the axial ratio $a : c = 1 : 1.447$. W. G. Mixter gave for the heat of formation $2Na_2O_2 + Sn = Na_2SnO_3 + Na_2O + 138$ Cals.; $(Na_2O, Sn, O_2) = 172.6$ Cals.; with crystalline stannic oxide, $(Na_2O, SnO_2) = 35.4$ Cals., and with the amorphous oxide, 37.1 Cals. E. Frémy, and E. Haeffely said the salt is more soluble in cold than in hot water; J. C. G. de Marignac said that 100 parts of water at 20° dissolve 50 parts of salt, and the same amount is dissolved by hot water; while, according to J. M. Ordway, 100 parts of water at 0° dissolve 67.4 parts of salt, and the sp. gr. of the soln. is 1.472 at 15.5°; whilst at 20°, 61.3 parts of salt are dissolved and the sp. gr. of the soln. is 1.438 at 15.5°. H. Zocher represented the percentage solubilities of the tri- and tetra-hydrates by the curves shown in Fig. 65. The transition point is near −5°. The trihydrate forms a eutectic with water at −11°, and the tetrahydrate at −7°. The *henicosihydrate*, $Na_2Sn(OH)_6.18H_2O$, has a transition point to the anhydrous salt $Na_2Sn(OH)_6$ at 1°. In normal soln., about 2.7 per cent. is hydrolyzed, and the reaction is complete with $\frac{1}{3000}N$-soln. The hydrolysis increases with time, as is also the case with some other colloidal soln.—*e.g.* stannic chloride. There was no evidence of an adsorption of alkali by sodium stannate. J. Bellucci and N. Parravano.

FIG. 65.—Solubility of Sodium Stannates.

said that the trihydrate gives off no water at 100°, but at 140°, it is decomposed. The contained water is assumed to be constitutional, forming $Na_2Sn(OH)_6$. The action of carbon dioxide is similar to the action of that gas on potassium α-stannate—*vide supra*. The salt dehydrated at 140° is a white powder which does not evolve heat when mixed with water at room temp., and shows no tendency to dissolve in that menstruum. H. Zocher prepared trihydrated **lithium stannate**, $Li_2SnO_3.3H_2O$, or $Li_2Sn(OH)_6$, and the pentahydrate, $Li_2Sn(OH)_6.2H_2O$, and the solubilities of the two hydrates are indicated in Fig. 66.
FIG. 66.—Solubilities of Lithium Stannates.

β-stannic acid is insoluble in ammonia, and *ammonium β-stannate* has not been made. E. Frémy obtained a number of **β-stannates** with varying proportions of $K_2O : SnO_2$. They have not been obtained in the crystalline state, and J. M. van Bemmelen regards them as adsorption products. J. J. Berzelius, and H. Rose reported $K_2O.10SnO_2$ to be formed by the action of very dil. potash-lye on β-stannic acid; H. Rose, and R. Weber made $K_2O.7SnO_2.3H_2O$, by the action of potassium hydroxide on a soln. of β-stannic acid; and E. Frémy, and R. Weber, $K_2O.6SnO_2.5H_2O$, by the action of much water on $K_2O.3SnO_2.3H_2O$, or by the action of dil. potash-lye on β-stannic acid; E. Frémy added potassium hydroxide to a soln. of β-stannic acid in potash-lye, and obtained what R. Engel regarded as the normal salt, **potassium β-stannate**, $K_2O.5SnO_2.4H_2O$. The product, dried on a porous tile, appears as a horny, translucent colloid. It is quite soluble in water, but cannot be crystallized. When heated with conc. alkali-lye, it forms the α-stannate. It is dehydrated at 130°, and is then completely soluble in water. It is decomposed at a red heat. E. Frémy reported $K_2O.3SnO_2.3H_2O$ to be formed as a gummy precipitate by adding alcohol to a conc. soln. of β-stannic acid in potash-lye. R. Engel reported *potassium parastannate*, $K_2Sn_5O_{11}.2(or\ 3)H_2O$, to be formed by the action of potassium hydroxide or parastannic acid (*q.v.*). E. Frémy reported the formation of **sodium β-stannate**, $Na_2O.5SnO_2.8H_2O$, by treating β-stannic acid with a conc. aq. soln. of sodium hydroxide. The sparingly soluble, crystalline powder is decomposed at 60°, or when boiled, forming β-stannic acid and sodium hydroxide. The salt was also prepared by E. Haeffely. R. Engel took advantage of the insolubility of sodium β-stannate in an excess of potash-lye to prepare pure β-stannic acid. C. T. Barfoed reported the formation of $Na_2O.9SnO_2.8H_2O$, by adding an excess of sodium hydroxide to a clear soln. of β-stannyl chloride; and washing the gummy mass with dil. aq. alcohol. It is insoluble in alcohol, and in sodium hydroxide.

C. Zulkowsky melted stannic oxide and potassium carbonate in the proportions $2SnO_2 : K_2CO_3$, and obtained what he regarded as $K_2Sn_2O_5$, or $KO.SnO.O.SnO.OK$, *i.e.* **potassium mesodistannate,** and said that the opacity produced by stannic oxide in glasses and enamels depends on the formation of this compound. A. Moberg prepared **ammonium α-mesodistannate**, $(NH_4)_2Sn_2O_5.nH_2O$, as a viscid mass, by evaporating over sulphuric acid a sat. soln. of stannic hydroxide in aq. ammonia; and J. J. Berzelius obtained a similar product by adding ammonium chloride to an aq. soln. of potassium stannate, and evaporating the soln. spontaneously. A. Ditte also obtained a hard, bony mass by evaporating the ammoniacal soln. of stannic hydroxide.

According to T. Leykauf, when a soln. of cupric nitrate is treated with a soln. of stannous chloride in potassium hydroxide, a yellowish-green precipitate is formed, which, if kept out of contact with air, becomes yellow, and then forms hydrated **cuprous α-stannate**—possibly $Cu_2SnO_3.nH_2O$—and on exposure to air forms a mixture of cupric hydroxide and stannic acid.

The dark green mineral called by T. Ulke *cuprocassiterite*, supposed to be produced by the oxidation of stannite, was regarded as having the composition $4SnO_2+Cu_2Sn(OH)_2$, and sp. gr. 4·534; W. P. Headden, however, showed that its composition varies widely.

According to F. Lenssen, if soln. of stannous and cupric oxides in potassium hydroxide be mixed, with the former in excess, cuprous oxide is deposited if the liquid be allowed to stand; but if boiled, *stannous cuprous stannate*, $3SnO.Cu_2O.SnO_2.5H_2O$, is deposited as a black or greenish-black powder. It loses 4·73 per cent. of water at 100°, and at a higher temp. is oxidized to cuprous stannate. Aq. ammonia, and dil. acids decompose it slowly; and with conc. hydrochloric acid, metallic copper, as well as cuprous, stannous, and stannic chlorides are formed.

A. Moberg mixed a soln. of a cupric salt and potassium stannate, and obtained green **cupric α-stannate,** $CuSnO_3.3H_2O$; L. Elsner described the preparation of a blue pigment on these lines. A. Ditte obtained small, pale blue crystals by adding a soln. of potassium stannate to an ammoniacal soln. of a cupric salt so long as the precipitate redissolves, and evaporating the liquid over sulphuric acid. He supposed the product to be the *tetrahydrate*. It dissolved readily in aq. ammonia. By treating the crystals with a conc. ammoniacal soln. of the mother-liquid at ordinary temp., dark blue crystals were obtained which were assumed to be **ammonium cupric α-stannate,** $(NH_4)_2O.CuO.SnO_2.2H_2O$. The crystals were sparingly soluble in cold water, and formed a green soln. with acids.

According to A. Ditte, soluble silver salts form with soluble stannous salts, characteristic, highly-coloured precipitates, the composition of which varies with the relative proportions of the reacting bodies. When the stannous salt is added to an excess of silver nitrate, a white precipitate is formed which rapidly becomes red, and eventually deep red, almost black. The filtrate is colourless, but after a short time deposits the same precipitate. Several hours are required for complete precipitation. The dark red precipitate is well washed and dried in a vacuum. It is **silver α-stannate,** $SnO_2.Ag_2O+2H_2O$, soluble in dil. nitric acid, but insoluble in ammonia. When heated, it loses water without detonation or incandescence, and becomes insoluble in dil. acids. J. Bellucci and N. Parravano also prepared the α-stannate. A. Ditte also found that when silver nitrate is added to an excess of stannous nitrate, a white precipitate is produced, which when dry forms a grey powder readily soluble in dil. nitric acid, insoluble in ammonia, but turned deep red by a trace of this reagent. If the white precipitate is left in the original liquid, it becomes red after some time. When suspended in a large quantity of water, it is converted into a deep red powder, which, when dried in a vacuum, is insoluble in ammonia, but soluble in dil. nitric acid. This red compound is **silver β-stannate,** $5SnO_2.Ag_2O$. If slowly formed in the original liquid, it contains the *heptahydrate*, but if formed by suspension in water, the *trihydrate*. Dried at 80°, it has a deep blue-black colour. When heated, it loses water and detonates, with development of heat and light. This detonation is transmitted along a train of the compound, as in the case of gunpowder. The anhydrous metastannate is insoluble in dil. acids, but warm conc. nitric acid dissolves out silver, leaving metastannic acid. When dil. stannous nitrate in slight excess is added little by little to silver nitrate, a deep reddish-purple precipitate is deposited after some time. This dissolves in nitric acid, forming a clear yellow soln., and also in ammonia, forming an intensely red liquid. When exposed to the air, the dil. ammoniacal soln. is completely decolorized after some time, but if it contains a moderate quantity of the silver salt, it deposits on evaporation a purple precipitate having all the properties of the original substance. When this precipitate is washed and dried, either in vacuum or at 30°, it forms small friable masses with a vitreous fracture, entirely soluble in cold dil. ammonia. In the formation of this compound, $5SnO_2.Ag_4O.2n(SnO_2,Ag_2O)+nH_2O$, a portion of the stannous salt is oxidized to stannic acid, and a portion of the silver salt is reduced to suboxide. The compound loses water when heated, and becomes insoluble in ammonia. The so-called *silver-purple* analogous to purple of Cassius was examined by G. F. C. Frick, H. Schulz, G. T. Fechner, N. W. Fischer, J. J. Berzelius, etc.—*vide* **3.** 23, 11. Similarly also for *gold purple*.

G. Tschermak obtained needle-like crystals of anhydrous **calcium α-stannate,** $CaSnO_3$, by melting together molar proportions of calcium and stannic oxides.

A. Ditte melted a mixture of stannic and calcium oxides and calcium chloride. The cold mass was treated with dil. hydrochloric acid, and the residue contained small transparent crystals—plates, and cubes of more or less altered octahedra. The salt is not attacked by dil. acids or by molten sodium hydroxide. According to A. Moberg, a hydrated form is slowly precipitated by adding a calcium salt to a soln. of potassium stannate; according to A. Ditte, the precipitate is transformed into well-formed crystals at 100°. A. Moberg regarded the salt as a *tetrahydrate*; A. Ditte, as a *pentahydrate*; and J. Bellucci and N. Parravano, as a *trihydrate* with a constitution $CaSn(OH)_6$ in conformity with the corresponding alkali salts (*q.v.*). The hydrate is stable in vacuo over sulphuric acid; it loses the following percentage amounts of water at the given temp. :

	100°	120°	140°	160°	200°
Loss	0·36	2·50	2·84	3·00	4·63

A prolonged heating to redness is needed to remove the water completely. A. Ditte said that the hydrate is insoluble in water, but soluble in nitric acid. C. Zulkowsky prepared what he regarded as a **calcium orthostannate,** Ca_2SnO_4, by heating at a pale yellow heat a mixture of the two oxides in the required proportions. The mass so produced hardens under water with a feeble evolution of heat. D. Balareff found that tin dioxide does not react with calcium oxide at 950°, but it does so rapidly with bárium and strontium oxides. G. Aminoff represented *nordenskjöldine*, $Ca(BO)_2SnO_4$—*calcium diborylstannate*—as having crystals with the axial ratio $a : c = 1 : 1·6442$—*vide* **5**. 32, 14.

J. Bellucci and N. Parravano prepared **strontium α-stannate,** $SrSnO_3.3H_2O$, or $SrSn(OH)_6$, by adding a sat. soln. of strontium hydroxide or chloride to a soln. of potassium stannate, and warming the gelatinous mass on the water-bath. The white crystalline powder is stable in vacuo over sulphuric acid; it loses 0·33 per cent. of water at 100°, and 0·97 per cent. at 140°. All three mols of water are completely expelled only at a red heat. A. Ditte obtained a similar substance by an analogous process and assigned to it the composition $3SrO.2SnO_2.10H_2O$. It was possibly the α-stannate contaminated with a little strontium hydroxide. A. Moberg, J. J. Berzelius, and A. Ditte mixed a soln. of a barium hydroxide or chloride with a soln. of potassium stannate, and obtained a heavy white powder. J. Bellucci and N. Parravano washed the precipitate with water at ordinary temp. and dried it first in air, and then over calcium chloride to a constant weight. J. J. Berzelius represented it by $BaO.4SnO_2.nH_2O$; A. Ditte, by $2BaO.SnO_2.10H_2O$; A. Moberg, by $BaSnO_3.6H_2O$; and J. Bellucci and N. Parravano, by $BaSn(OH)_6$. $4H_2O$, or **heptahydrated barium α-stannate,** $BaSnO_3.7H_2O$. At 100°, it loses 17·17 per cent. of water, forming the *trihydrate;* at 120°, it loses 19·29 per cent.; at 140°, 20·85 per cent.; at 160°, 21·62 per cent.; at 180°, 22·55 per cent.; at 200°, 23·80 per cent. It is sparingly soluble in water, and readily soluble in nitric acid. J. A. Hedvall and N. von Zweigbergk did not observe any reaction between barium dioxide and stannic oxide when a mixture of the two was heated, but D. Balareff found a slight heat effect when a mixture of barium and stannic oxides was heated. H. Zocher examined some properties of barium stannate.

A. Moberg added a magnesium salt soln. to one of potassium stannate and obtained a slimy precipitate—probably **magnesium α-stannate,** $MgSnO_3.nH_2O$. A. Ditte reported **zinc α-stannate,** $ZnSnO_3.2H_2O$, to be formed when a soln. of a zinc salt is added to one of potassium stannate; and $3ZnO.2SnO_2.10H_2O$, by treating an ammoniacal soln. of zinc sulphate with one of potassium stannate. The small, clear, colourless crystals are soluble in dil. acids; but after dehydration they are insoluble. A. Moberg added a soln. of mercurous nitrate to one of potassium stannate, and obtained a yellow precipitate of **mercurous α-stannate,** with the composition $Hg_2SnO_3.5H_2O$ when dried over sulphuric acid; it soon turned green. By using mercuric nitrate in a similar way, he obtained white mercuric **α-stannate,** $HgSnO_3.6H_2O$, which soon became dark green.

J. J. Berzelius found that when an alloy of lead and tin is drossed in air, it oxidizes much more readily than either metal alone, " the change being accelerated by the affinity which the two oxides have for one another." An alloy of tin with 4 or 5 times its weight of lead burns in air like charcoal, the combustion afterwards proceeds spontaneously like low-grade peat. According to R. W. Fox, the presence of platinum retards the oxidation, but gold has no adverse effect and is at the same time oxidized, forming purple of Cassius. The product of the oxidation of the tin-lead alloy was once called **lead stannate**, but it is probably only a mixture. That obtained from an alloy approximating solder in composition is called *tin-ash*, *putty-powder*, or *potée d'etain*, and the commercial product approximates 30 per cent. stannic oxide and 70 per cent. lead oxide. The powder is used for polishing and as an opacifying agent in enamels. A. Moberg said that when a lead salt is added to a soln. of potassium stannate, there is but a slight precipitation of lead stannate owing to the solubility of that salt.

A. Moberg, and J. J. Berzelius obtained white, pulverulent **manganese α-stannate** by mixing soln. of manganese salt and potassium stannate. The white colour changes to dark brown on exposure to air. According to C. Fromherz, potassium permanganate gives no precipitate with stannous chloride. J. J. Berzelius mixed soln. of potassium stannate and of a cobalt salt, and obtained a blue precipitate which, when washed and dried, became dark brown. After heating white hot, the colour was blue. A. Ditte mixed a soln. of potassium stannate with an ammoniacal soln. of a cobalt salt and obtained a pulverulent precipitate which redissolved in the ammoniacal liquor. If the stannate is added until the precipitate no longer dissolves, and the clear soln. be evaporated, rose-red crystals of **cobalt α-stannate,** $CoSnO_3.6H_2O$, are formed. A. Ditte obtained pale green cubic crystals of **nickel α-stannate,** $NiSnO_3.5H_2O$, by an analogous process. J. A. Hedvall prepared green **cobalt orthostannate,** Co_2SnO_4, by heating a mixture of the constituent oxides; and likewise also **nickel orthostannate,** Ni_2SnO_4. M. Rüger also made some observations on this subject.

According to N. W. Fischer, the precipitate which is produced when soln. of stannous chloride and hydrochloroplatinic acid are mixed is probably **platinous α-stannate.** According to R. Schneider, **platinum distannyl α-stannate,** $Pt(SnO)_2SnO_3$, is formed by mixing soln. of hydrochloroplatinic acid and a soln. of stannous chloride in dil. hydrochloric acid ; and also by the action of stannous chloride on a soln. of platinic chloride which has been decolorized with sulphur dioxide. The washed precipitate appears as a black powder when dried. It loses water when heated. It is decomposed by alkali-lye, forming stannic oxide and an alkali platinate. A dil. soln. of sodium hydroxide extracts some tin oxide and leaves residual sodium platinic stannyl stannate, $Na_2O.2PtO.SnO.SnO_2$. L. Wöhler considers that the assumed platinum distannyl α-stannate is nothing but *platinum purple*, an adsorption product of stannic hydroxide and colloidal platinum—*vide* **3.** 23, 11. Platinum purple has been studied by L. Wöhler, and B. Delachanal and A. Mermet. According to A. Ditte, palladium nitrate, added to an excess of stannous salt, forms very deep brown **palladium β-stannate,** $5SnO_2.PdO.4H_2O$, insoluble in ammonia, but soluble in hydrochloric acid, forming a deep brown soln., and in nitric acid, forming a reddish-yellow soln. Platinum chloride under similar conditions forms a blood-red **platinum β-stannate,** $5SnO_2.PtO+4H_2O$, insoluble in ammonia, but soluble in hydrochloric acid, forming a beautiful red soln., and in nitric acid, forming a yellowish soln. Both these compounds when heated lose their water with detonation and incandescence, and become insoluble in dil. acids. If the palladium or platinum salt is in excess, highly coloured stannates, soluble in dil. acids, are formed. When heated, these lose their water without deflagration, and become insoluble in dil. acids. A. Michel-Lévy and L. Bourgeois obtained a product with a composition approaching $PtO_2.4SnO_2$, in yellow hexagonal plates resembling muscovite gold, and sp. gr. 6·70, by melting at a white heat in a platinum crucible a mixture of precipitated

stannic acid and sodium carbonate for 15 mins. The cold mass is lixivated with water, washed with water acidified by nitric acid, and dried. Boiling conc. acids attack the product with difficulty. At a dull red heat, hydrogen reduces it to Pt_4Sn_3.

A fine pink colour [2]—*chrome-tin pink*—is developed when a mixture of stannic oxide and a very small proportion of chromic oxide is calcined at a high temp. in an oxidizing atm. ; at a lower temp. the colour is lilac. If some calcium carbonate is present, the pink colour develops at a lower temp. The cause of the coloration has been the subject of much speculation ; *chromium stannates*, and stannic chromates with the required properties have been invented. The coloration probably is related to the chrome-alumina crimson of the ruby, and purple of Cassius in that finely divided chromic oxide is deposited on the stannic oxide.

§ 15. The Fluorides of Tin and the Fluostannates

C. W. Scheele [1] found that aq. hydrofluoric acid has no sensible action on tin even when warmed, while a soln. of stannous oxide dissolves in that acid ; and J. L. Gay Lussac and L. J. Thénard, that when evaporated out of contact with air, it yields small white crystals of **stannous fluoride,** SnF_2. E. Frémy obtained the salt by the action of hydrogen fluoride, or of hydrofluostannous acid on stannous oxide. O. Unverdorben added a soln. of ammonium fluoride to one of stannous chloride, and found that lamellar plates of stannous fluoride were precipitated. J. J. Berzelius also obtained opaque prisms of the salt, which, according to J. C. G. de Marignac, belong to the monoclinic system, and have axial ratios $a : b : c = 2\cdot7204 : 1 : 1\cdot4078$, and $\beta = 109° \ 24'$. The salt has an acid taste. J. J. Berzelius said that when exposed to air, the salt is transformed into **stannic oxyfluoride,** $SnOF_2$. J. L. Gay Lussac and L. J. Thénard said it is easily soluble in water ; and O. Unverdorben, in an aq. soln. of potassium hydroxide. According to L. R. W. McCay, when hydrogen sulphide is passed into a soln. of stannous fluoride containing free acid, stannous sulphide is formed in the presence of much free sodium acetate ; stannic fluoride under similar conditions gives no precipitate. E. Frémy said that an excess of hydrofluoric acid and stannous oxide react, forming **hydrofluostannous acid,** H_2SnF_4, or $2HF.SnF_2$. According to R. Wagner, a soln. of stannous hydroxide in one of ammonium hydrofluoride furnishes crystals of **ammonium fluostannite,** $(NH_4)_2SnF_4.2H_2O$; and with potassium hydrofluoride, crystals of **potassium fluostannite,** $K_2SnF_4.2SnF_2.H_2O$, are formed.

According to J. L. Gay Lussac and L. J. Thénard,[2] when a soln. of stannic oxide in hydrofluoric acid is evaporated, an insoluble basic fluoride is formed ; and, according to J. J. Berzelius, when the soln. of stannic oxide in hydrofluoric acid is boiled, it coagulates like the white of an egg. H. Moissan said that at low temp., tin is not attacked by fluorine, but at 100°, white stannic fluoride is formed with incandescence. O. Ruff and W. Plato prepared **stannic fluoride,** SnF_4, by adding stannic chloride to anhydrous hydrofluoric acid, when a vigorous reaction occurs. The mixture was allowed to stand over-night in a vessel cooled by ice, and at room temp. for 4 hrs. It was then kept at 100° for a couple of days or until no more hydrogen chloride was given off. The temp. of the mixture was kept between 130° and 220°, to drive off stannic chloride. The residue has the composition $SnCl_4.SnF_4$, and it decomposes at a red heat with the evolution of stannic chloride. At 750°, the stannic fluoride sublimes. Thirty grams of stannic chloride gave 17 grms. of the fluoride. According to O. Ruff and W. Plato, stannic fluoride forms a snow-white crystalline mass of sp. gr. 4·780, and b.p. 705°. The salt is very hygroscopic, and dissolves in water with a hissing noise. When the soln. is boiled, or allowed to stand for some days, it deposits hydrated stannic oxide. N. H. Furman found stannic fluoride is more resistant than stannic chloride towards hydrolysis. The presence of hydrofluoric acid and of alkali fluorides hinders the precipitation of tin by hydrogen sulphide. J. J. Berzelius said that it reacts with silicon tetrafluoride, forming the complex $SiF_4.SnF_4$, **silicon tin octofluoride.** O. Ruff and C. Albert found that it reacts with silicon hydrotrichloride at 200°, forming tin tetrachloride and silicon hydrotrifluoride, $SiHF_3$.

J. C. G. de Marignac showed that it forms a number of complex **fluostannates** isomorphous with the corresponding fluosilicates and fluotitanates, being salts of the hypothetical hydrofluostannic acid, H_2SnF_6. R. D. Hall and E. F. Smith found that when dissolved in sulphuric acid, the fluostannates do not react with morphine, codeine, resorcine, etc., like the fluotitanates. J. C. G. de Marignac prepared **ammonium fluostannates,** $(NH_4)_2SnF_6$, by treating ammonium stannate with hydrofluoric acid ; but it is much easier to make the salt by the action of ammonium fluoride or sulphate on silver or lead fluostannate. The salt seldom forms good crystals. The crystals belong to the trigonal system and have the

axial ratio $a:c=1:0.8062$. The birefringence is negative. By adding ammonia and hydrofluoric acid to a soln. of the normal fluostannate, **tetrammonium octofluostannate**, $4NH_4F.SnF_4$, is formed. This salt loses ammonium fluoride below $100°$; and the soln. does not effervesce with ammonium carbonate. J. C. G. de Marignac made **lithium fluostannate**, $Li_2SnF_6.2H_2O$, by the action of hydrofluoric acid on lithium stannate. The monoclinic prisms have the axial ratios $a:b:c$ $=1.235:1:2.160$, and $\beta=118°\ 0'$. He obtained normal **sodium fluostannate**, Na_2SnF_6, as a crystalline crust by evaporating a soln. of the alkali stannate neutralized with hydrofluoric acid. The salt is probably isomorphous with the fluotitanate, 100 parts of water dissolve about 5.5 parts of salt at $20°$. J. C. G. de Marignac made **potassium fluostannate**, $K_2SnF_6.H_2O$, in an analogous way, the white crystalline plates resembling talc. These monoclinic crystals—the α-salt—have the axial ratios $a:b:c=0.9924:1:1.0520$, and $\beta=98°\ 42'$. H. Töpsöe gave 3.053 for the sp. gr.; 100 parts of water at $18°$ dissolve 6.7 parts of salt, and 100 parts of boiling water, 43.9 parts of salt. At the same time, rhombic octahedral crystals—the β-salt—having the same composition are formed; 100 parts of water dissolve 3.7 parts of salt at $18°$, and 100 parts of boiling water, 33.3 parts of salt. If the α-salt be digested at a gentle heat with insufficient water for complete soln., and preferably in the presence of a few drops of hydrofluoric acid, it passes into the β-salt. The latter is the stable form. The β-salt crystallizes unchanged on evaporating the soln. at a gentle heat; but if a little potassium hydroxide is present, the α-salt is formed. According to F. Emich, the β-salt is obtained by mixing soln. of 27 grms. of stannic chloride in 270 c.c. of water and of 57 grms. of potassium fluoride in 170 c.c. of water. The dry crystals do not attack glass. J. C. G. de Marignac said the salt loses all its water at a little over $100°$, and that it melts at a red heat with the loss of hydrogen fluoride. He also obtained monoclinic prisms of potassium hydrohexafluostannate, $3KF.SnF_4.HF$, or $K_2SnF_6.KHF_2$, with the axial ratios $a:b:c=0.6277:1:0.4928$, and $\beta=93°\ 0'$. They lose very little weight at $100°$; at $250°$–$300°$, 5.40 per cent. is lost. The soln. effervesces with ammonium carbonate, but no precipitate is formed until the soln. is quite neutralized. A. Skrabel and J. Gruber prepared **rubidium fluostannate**, Rb_2SnF_6, by adding a soln. of the carbonate to a soln. of stannic acid in 40 per cent. hydrofluoric acid, and allowing the salt to crystallize. The hexagonal plates are optically negative and uniaxial; they made **cæsium fluostannate**, Cs_2SnF_6, in a similar manner. The hexagonal plates are optically uniaxial and negative.

J. C. G. de Marignac made blue, monoclinic, prismatic crystals of **copper fluostannate**, $CuSnF_6.4H_2O$, with axial ratios $a:b:c=0.7535:1:0.5591$, and $\beta=104°\ 10'$. The crystals of the corresponding **silver fluostannate**, $Ag_2SnF_6.4H_2O$, are so deliquescent that crystallographic data were not obtained. He made **calcium fluostannate**, $CaSnF_6.2H_2O$, by treating calcium stannate with hydrofluoric acid, or potassium fluostannate with calcium chloride, and evaporating the soln. at a gentle heat. The badly formed crystals belong to the monoclinic system having the axial ratios $a:b:c=1.236:1:—$, $\beta=110°\ 54'$. The crystals are not altered at $100°$, but lose water and hydrogen fluoride at a higher temp., forming a mixture of stannic oxide and calcium fluoride. The corresponding **strontium fluostannate**, $SrSnF_6.2H_2O$, forms small monoclinic crystals with the axial ratios $a:b:c=1.22:1:—$, and $\beta=111°\ 9'$. They are isomorphous with the corresponding fluosilicate; they do not lose water at $100°$, but are decomposed at a higher temp. At $18°$, 100 parts of water dissolve 18.2 parts of salt. Small crystals of anhydrous **barium fluostannate**, $BaSnF_6$, were obtained in an analogous manner; they resemble barium fluosilicate. If a dil. aq. soln. of the anhydrous salt be slowly cooled, or spontaneously evaporated, plates of the *trihydrate*, $BaSnF_6.3H_2O$, are formed, resembling boric acid. F. Emich obtained the salt by mixing aq. soln. of stannic chloride and barium fluoride. According to J. C. G. de Marignac, the monoclinic crystals have the axial ratios $a:b:c=0.739:1:0.834$, and $\beta=105°\ 30'$.

At 18°, 100 parts of water dissolve 5·6 parts of salt. F. Emich said the crystalline salt attacks glass.

J. C. G. de Marignac obtained trigonal crystals of **magnesium fluostannate,** $MgSnF_6.6H_2O$, which were stable in air. The corresponding crystals of **zinc fluostannate,** $ZnSnF_6.6H_2O$, had the axial ratio $a:c=1:0.5190$, and $a=112°\ 7'$. The cleavage was perfect. B. Gossner gave 2·445 for the sp. gr., and he measured the sp. gr. of mixtures with the isomorphous molybdenato-fluoride, $ZnMoO_2F_4.6H_2O$. When heated, the salt loses water and hydrofluoric acid. Trigonal crystals of **cadmium fluostannate,** $CdSnF_6.6H_2O$, were obtained in an analogous manner. The trigonal crystals of **manganese fluostannate,** $MnSnF_6.6H_2O$, obtained in an analogous way, have the axial ratio $a:c=1:0.5161$, and $a=111°\ 12'$. They gradually effloresce in air. The corresponding **nickel fluostannate,** $NiSnF_6.6H_2O$, forms trigonal crystals with the axial ratio $a:c=1:0.5245$, and $a=112°\ 14'$. By treating lead stannate with hydrofluoric acid, J. C. G. de Marignac obtained thin 4- or 8-sided plates of **lead fluostannate,** $PbSnF_6.3H_2O$, corresponding with the barium salt. The monoclinic prisms have the axial ratios $a:b:c=0.7485:1:0.8549$, and $\beta=104°\ 18'$.

§ 16. The Stannous Chlorides

Tin furnishes two types of chloride corresponding with the oxides—stannous chloride, $SnCl_2$, and stannic chloride, $SnCl_4$. Each of these forms hydrates, and hydrochlorides. The two chlorides were not clearly distinguished until B. Pelletier's [1] investigation : *Sur plusiers propriétés du muriate d'étain*, in 1792. The so-called *tin trichloride* obtained by J. N. von Fuchs, and J. J. Berzelius, by dissolving tin sesquioxide in hydrochloric acid, is probably a mixture of stannous and stannic chlorides. Anhydrous **stannous chloride,** $SnCl_2$, was formerly called *butter of tin,* and it was made by gradually heating tin or tin amalgam with mercurous or mercuric chloride, when the mercury volatilizes ; it was also made by heating tin in a stream of hydrogen chloride : $Sn+2HCl=SnCl_2+H_2$; and A. Ditte [2] made it by heating stannous sulphide under similar conditions : $SnS+2HCl=SnCl_2+H_2S$. According to J. Kelley and E. F. Smith, the continued action of the hydrogen chloride in the cold completely converts stannous sulphide into chloride without any volatilization. It is, however, impossible to separate stannous and stannic sulphides by this method, as heat is necessary to drive out the stannic salt, and this causes a partial volatilization of the stannous salt. Stannous chloride can be made by heating the dihydrated $SnCl_2.2H_2O$ in a closed vessel, gradually to redness ; the anhydrous chloride distils over after the water has been expelled. H. Capitaine gently heated the dihydrate in a capacious crucible until frothing ceased. The molten mass remaining was poured into a small crucible and the cold mass coarsely powdered and heated in a glass retort. The first fraction which distils over is stannous chloride, and the last fraction may contain iron chloride,

and requires a second distillation to free it from that impurity. T. Rondelli heated the ore with carbonaceous matter and chlorine; with carbon monoxide and chlorine or hydrogen chloride; or with carbonyl chloride.

If a soln. of tin in warm hydrochloric acid, or if a soln. of stannous chloride in dil. hydrochloric acid be evaporated and cooled, crystals of **dihydrated stannous chloride,** $SnCl_2.2H_2O$, also called *tin salt,* are formed. C. Nöllner, and E. Bérard described the preparation on a large scale in copper or stoneware vessels. A. Scheurer-Kestner described the preparation of the salt from a soln. of stannous hydroxide or sulphide in hydrochloric acid. The dihydrate was analyzed by J. C. G. de Marignac, F. Penny, and T. H. Henry. The analysis of commercial tin salt was discussed by W. Minor, and F. Dietze. A. Ditte reported that small crystals of **monohydrated stannous chloride,** $SnCl_2.H_2O$, are formed by the action of hydrogen chloride on crystals of the dihydrate, and afterwards fusing and cooling the product. A. Scheurer-Kestner said that **tetrahydrated stannous chloride,** $SnCl_2.4H_2O$, is formed when a mol of stannous hydroxide is dissolved in a mol of stannic chloride of sp. gr. 1·8, and the soln. cooled in ice-water; if more stannous hydroxide is used, the dihydrate is produced. C. T. Gerlach could not make the tetrahydrate.

The physical properties of the stannous chlorides.—Anhydrous stannous chloride appears as a white or greyish-white translucent mass with a conchoidal fracture; and when cooled after fusion, C. M. Marx found that it becomes syrupy and then solidifies. According to A. E. Nordenskjöld, the sublimed **crystals** are colourless and belong to the rhombic system, with axial ratios $a : b : c = 0.7366 : 1 : 1.0680$. The crystals of the dihydrate are transparent colourless prisms, which were found by J. C. G. de Marignac to belong to the monoclinic system, and to have the axial ratios $a : b : c = 1.2888 : 1 : 1.2452$, and $\beta = 114° 58'$. The anhydrous salt was analyzed by J. Davy, and V. and C. Meyer; and the dihydrate by J. C. G. Marignac, F. Penny, and T. H. Henry. J. J. Berzelius' analysis made the dihydrate a monohydrate, and E. Turner's, a trihydrate.

F. Penny found the **specific gravity** of the dihydrate to be 2·710 at 15·5°, and F. W. Clarke, 2·634 at 24°. According to A. Michel and L. Kraft, the sp. gr. of a sat. aq. soln. at 15° is 1·827, and C. T. Gerlach found the sp. gr. of soln. containing ω per cent. of $SnCl_2.2H_2O$, at 15°.

ω	.	.	2	10	20	30	40	50	60	70	75
Sp. gr.	.	.	1·013	1·068	1·144	1·230	1·330	1·445	1·582	1·745	1·840

W. Biltz and E. Birk gave 3·952 for the sp. gr. of fused stannous chloride at 25°/4°, and 47·98 for the mol. vol. W. Klemm and W. Biltz gave for the sp. gr., D, of the molten chloride at $\theta°$, $D = 3.394 - 0.00120(\theta - 245°)$ between 278° and 556°; and for the vol., v, at $\theta°$ when v_m is the vol. at the m.p., $v = v_m\{1 + 0.00036(\theta - 245)\}$; the mol. vol. at the m.p. is 55·9 and at 25°, 48·00. R. Lorenz and W. Herz gave 3·367 for the sp. gr. and 56·31 for the mol. vol. at the m.p. F. Ephraim studied the vol. contraction attending the formation of the tin halides; and I. I. Saslawsky found 0·98 for the ratio of the mol. vol. to the sum of the at. vol. of the constituents. S. Motylewsky found the **drop-weight** of stannous chloride to be 111 mgrms. when that of water at 0° is 100 mgrms. The **vapour density** of stannous chloride was found by R. Rieth to be variable; V. and C. Meyer gave 12·96 at 619°–697° when referred to air, and this agrees with the formula Sn_2Cl_4; T. Carnelley said the temp. at which vap. density was made was here too close to the b.p., and other observations by V. Meyer and H. Züblin, and H. Biltz and V. Meyer gave:

—		639°	678°	699°	759°	790°	113°
Vap. density	.	8·85	8·57	8·49	8·26	7·7	7·08

This makes it probable that Sn_2Cl_4 does not represent the mol. state of the vap., although the numbers are a little high for the normal $SnCl_2$ mol. A. Werner found from the raising of the b.p. of pyridine, the mol. wt. in that solvent is 202·89, and

in ethyl sulphide, 176—the calculated value for $SnCl_2$ is 189. J. Schröder and H. Steiner found the mol. wt. is half the normal value with very dil. soln. of stannous chloride in boiling methyl acetate. N. Castoro found the mol. wt. is normal for $SnCl_2$ during the freezing of soln. in urethane.

According to R. Lorenz and W. Herz, the coeff. of **thermal expansion,** a, of the molten salt is 0·000319 ; and the relation $aT_m = 0·166$ is in line with that for related chlorides. According to W. D. Bancroft and H. B. Weiser, stannous chloride is decomposed in the bunsen flame furnishing a deposit of metallic tin. A. Juliusberger measured the **vapour pressure,** p mm., of stannous chloride ; and C. G. Maier found :

	372·7°	447·8°	499·4°	536·2°	563·1°	596·6°	617·5°	633·9°	641·0°
p	10·2	56·4	116·6	205·3	346·9	537·5	706·3	882·0	972·4

According to J. Davy, anhydrous stannous chloride boils at a red heat with partial decomposition ; T. Carnelley and W. Williams gave 617°–628° for the **boiling point ;** H. Biltz and V. Meyer, 606·1° ; C. G. Maier, 622·8° ; F. Freyer and V. Meyer, 606° ; T. Karantassis, 245° ; J. McCrae, 603·25° ; and A. Helfenstein, 606°. T. H. Henry found that the dihydrate loses water over sulphuric acid in vacuo. A. Vogel found that when the anhydrous chloride is strongly heated, stannic chloride is given off, then stannous chloride, and a black mass remains which dissolves in hydrochloric acid, forming stannous chloride and hydrogen ; when the hydrated salt is heated it gives off water and hydrogen chloride, and a little chlorine ; while an oxychloride remains. If air be excluded, the salt can be dehydrated with but little hydrolysis. C. T. Gerlach found a sat. aq. soln. boils at 121·7°. J. A. Muller calculated the degree of polymerization in the critical state to be 1·404. L. Graetz gave 250° for the **melting point** of stannous chloride ; O. Menge, 245° ; G. Hermann, 247·2° ; and J. Kendall and co-workers, 246·8° ; while F. Penny gave 37·7° to 40·5° for the dihydrate. H. V. Regnault found the **heat of vaporization** of stannous chloride to be 46·84 Cals. C. G. Maier gave for the mol. heat of vaporization, 21,100 cals. at 622·8° and at 371·4°. H. V. Regnault found the **specific heat** between 20° and 99° to be 0·10162. J. Thomsen found the **heat of formation,** $(Sn,2HCl_{gas}) = 36·4$ Cals., and $(Sn,Cl_2) = 80·79$ Cals. with solid stannous chloride ; $(SnCl_2,2H_2O) = 5·72$ Cals. at 18° ; and for the **heat of solution,** $SnCl_2.2H_2O + Aq.$, 53·7 Cals., and $(SnCl_2,Aq.) = 350$ Cals. T. H. Henry found that the dissolution of the dihydrate in 100 c.c. of water lowers the temp. from 14·4° to −2·8°. W. Biltz and W. Fischer found the heat of soln. of stannous chloride in one per cent. hydrochloric acid to be 0·9 Cal. G. P. Drossbach investigated the ultra-red **absorption spectrum ;** and W. Jevons, the band spectrum. J. O. Perrine found no **fluorescence** in the ultra-violet rays. S. W. Young measured the **electrical conductivity** of hydrochloric acid soln. of stannous chloride. L. Graetz gave for the electrical conductivity of stannous chloride k, referred to mercury=1 :

	140°	160°	190°	200°	240°	250°	260°	300°	350°
$k \times 10^8$	6	12·5	60	360	5500	6650	7600	9600	10320

W. Klemm and W. Biltz gave 0·002 to 0·014 mho for the conductivity of the solid chloride between 222° and 244° ; and for the molten chloride, 0·89 mho at 263° ; 1·12, at 302° ; 1·18, at 314° ; 1·42, at 353° ; and 1·72, at 411° ; and the mol. conductivity, μ, at $\theta°$ is $\mu = 43·8 + 0·350(\theta - 245)$. Contrasted with stannic chloride, the electrical conductivity of stannous chloride is very high ; and G. von Hevesy noted in general a, marked change in the b.p. and conductivity when an element changes its valency. K. F. Ochs measured the oxidation potential of hydrochloric acid soln. of stannous chloride. G. Tammann studied the electrode potential of magnesium, manganese, aluminium, thallium, zinc, cadmium, lead, and iron in contact with fused stannous chloride. S. Meyer found the **magnetic susceptibility** of stannous chloride to be $-0·334 \times 10^{-6}$ per gram, or $-0·055 \times 10^{-6}$ per mol., or $-0·29 \times 10^{-6}$ mass units at 18° ; and G. Quincke, $-0·07 \times 10^{-6}$ mass units.

The **solubility** of anhydrous stannous chloride in water is high, and the dihydrate is formed ; the dihydrate is also readily dissolved by water. According to R. Engel, 100 parts of water at 0° dissolve 83·9 parts of stannous chloride, while A. Michel and L. Kraft found that at 15°, 100 c.c. of a sat. soln. contain 133·3 grms. of $SnCl_2$, and 49·4 grms. of water. R. Engel found that the solubility in water is diminished by the presence of a small proportion of *hydrochloric acid*, but increased by a large proportion ; H. Capitaine found the anhydrous salt is readily dissolved by *alcohol ;* and M. de Jong, by *ether*. According to A. Naumann, at 18°, a sat. soln. of stannous chloride in *acetone* contains 1·8 grms. of acetone for every gram of stannous chloride, and the soln. has a sp. gr. 1·6 at 18°. Stannous chloride is also soluble in *pyridine*, and *acetic ether*. A. Werner investigated the solubility in pyridine. Boiling *methyl acetate* was found by J. Schröder and H. Steiner to dissolve 15·7 per cent. of stannous chloride. F. L. Shinn said the salt is insoluble in *ethylamine*. V. Meyer found the dihydrate is easily soluble in alcohol, and J. Thiele and O. Dimrot, in glacial *acetic acid*. O. Aschan found 100 grms. of 95 per cent. *formic acid* dissolve 4·1 grms. of stannous chloride at 19°. S. von Laszczynsky found 100 parts of *ethyl acetate* dissolve 31·2 grms. of the dihydrate at —2° ; 35·5 grms. at 22° ; and 73·4 grms. at 82°.

The chemical properties of the stannous chlorides.—F. de Carli studied the reduction of stannous chloride by **hydrogen**. H. Capitaine said that anhydrous stannous chloride is fairly stable in air ; only a little oxidation could be detected in 3 weeks, and the product was quite soluble in water. When heated to its b.p., a mixture of stannic and stannous chlorides is distilled over, and a yellow oxychloride remains ; H. Schulze also found that when stannous chloride is heated in **oxygen,** stannic chloride and oxide are formed. According to M. Berthelot, when stannous chloride and oxygen are heated in a sealed tube to 500°, the reaction can by symbolized $SnCl_2 + O = SnOCl_2 + 50·4$ Cals. N. W. Fischer found that hydrated stannous chloride absorbs atm. oxygen and forms an oxychloride. If the aq. soln. be exposed to the air, the turbid soln. becomes clear, and acquires a yellow colour. The reaction is slower the more conc. the soln. H. Capitaine made observations on this subject, and J. W. Mallet said that a fairly conc. soln. of stannous chloride when kept over a year became turbid, and deposited a transparent gelatinous colloid of a yellowish colour, which, when washed, and dried at atm. temp., had a composition corresponding with what he called *chlorostannic acid*, $HO.SnO.Cl$. To preserve the aq. soln. from oxidation, C. F. Mohr recommended keeping some tin immersed in the liquid ; or protecting it from air—say, by covering the liquor with a layer of petroleum ; or, according to H. Morgan, keeping it in an atm. of coal-gas. J. Löwenthal found that an aq. soln. of stannous chloride was not oxidized when oxygen was passed through the liquid, or by a soln. of oxygen in water ; but it was oxidized in the presence of a little potassium permanganate or dichromate. A. Scheurer-Kestner showed that oxygen is absorbed by dil. soln. of stannous chloride, forming stannic chloride, and stannic acid ; but with conc. soln. oxygen is not absorbed. S. W. Young showed that the oxidation of aq. soln. of stannous chloride is promoted by caoutchouc, sulphur, ferrous sulphate, and cupric sulphate ; and retarded by manganous salts, some alkaloids, and potassium cyanide. The first stage of the process of oxidation involves the formation of stannic chloride, and this is then hydrolyzed, forming an oxychloride. Strongly alkaline soln. of stannous chloride are oxidized by atm. oxygen in a normal way without showing any signs of the activation of the oxygen. M. C. Boswell and J. V. Dickson found that fused sodium hydroxide oxidizes stannous chloride with the evolution of hydrogen. A. W. Francis measured the velocity of oxidation of stannous chloride. N. R. Dhar found that the oxidation of stannous chloride simultaneously induces the oxidation of soln. of sodium arsenite, formate and oxalate ; and that the oxidation of stannous salts by air is retarded by easily oxidizable substances like hydroquinone, sugars, glycerol, sodium arsenite, and some organic substances. N. N. Mittra and N. R. Dhar found the oxidation of a soln. of stannous chloride

in air favours the simultaneous oxidation of ferrous ammonium sulphate, and is favoured by the simultaneous oxidation of sulphurous acid.

The solubility of stannous chloride in **water,** and the formation of hydrated stannous chlorides have been previously discussed. According to N. W. Fischer, when stannous chloride is dissolved in a little air-free water, the soln. remains clear, but becomes turbid when dil. owing to the formation of an oxychloride. The soln. remains clear in the presence of hydrochloric or tartaric acid, or ammonium chloride ; and N. W. Fischer showed that the aq. soln. is hydrolyzed when heated to 200° in a sealed tube, and a yellow flocculent oxychloride is produced. J. L. Proust reported stannous oxychloride to be formed by treating a soln. of stannous chloride with insufficient potash-lye for complete precipitation. J. Davy used a similar process, and his analysis of the washed and dried product corresponded with **stannous oxychloride,** $SnO.SnCl_2.3H_2O$, or $Sn_2OCl_2.3H_2O$. A. Ditte obtained crystals of what was regarded as the same salt, but with four mols of water, $Sn_2OCl_2.4H_2O$, by treating the $3SnO.SnCl_2.6H_2O$ salt with a soln. of stannous chloride. According to J. Davy, this compound decomposes when heated, forming water, hydrochloric acid, stannous chloride and its hydrate, and stannous oxide. It froths vigorously when treated with conc. nitric acid ; it gives off hydrogen chloride when treated with conc. sulphuric acid ; and it dissolves without effervescence, forming stannous salts when treated with hydrochloric, acetic, dil. nitric or dil. sulphuric acid. H. F. Keller found small acicular or tabular crystals of stannous oxychloride, Sn_2OCl_2, lining the cavities in some metal objects in the aboriginal cemetery, Hogtown Bayou, Florida. A. Ditte emphasized that in preparing stannous oxychloride by the hydrolysis of stannous chloride, the soln. should be protected from air. He reported that **stannous tetraoxydichloride,** $4SnO.SnCl_2.6H_2O$, is produced as a gelatinous precipitate from an aq. soln. of stannous chloride ; and when digested in an aq. soln. of stannous chloride, it furnishes a white crystalline powder of **stannous trioxytetrachloride,** $3SnO.2SnCl_2.6H_2O$. This product is sparingly soluble in water, and readily soluble in dil. acids. All the stannous oxychlorides are decomposed by hot water, forming stannous oxide. According to C. M. Carson, **stannous tetradecahydroxytetrachloride,** $2SnCl_2.7Sn(OH)_2$, is the most basic of all the basic stannous chlorides. A slightly variable, crystalline material of approximately **trihydrated stannous pentoxyhexachloride,** $3SnCl_2.5SnO.3H_2O$, is the precipitate commonly formed by the action of boiling potassium hydroxide on an excess of stannous chloride, and there is no compound of intermediate composition. The precipitates usually formed by the action of water on stannous chloride contain such a large proportion of stannic compound that the analyses are of no value in ascertaining the composition of the basic stannous chlorides.

According to M. Berthelot, **chlorine** converts stannous chloride into stannic chloride, $SnCl_2+Cl_2=SnCl_{4liq.}+48\cdot8$ Cals. ; and in aq. soln., $SnCl_{2aq.}+Cl_2 =SnCl_{4aq.}+72-78\cdot2$ Cals. A. Ladenberg found that with **bromine,** anhydrous stannous chloride forms the dichlorodibromide ; while in aq. soln., S. W. Young and M. Adams found that stannic salts are formed. A. W. Francis studied the speed of the reaction. C. Lenormand showed that **iodine** has no perceptible action at ordinary temp. on stannous chloride, but when the two substances are in contact, the stannous chloride gradually becomes pale red. V. Thomas showed that anhydrous stannous bromide decolorizes a soln. of iodine in carbon disulphide, and on evaporation a mixture of stannic iodide and iodine trichloride is formed, but no dichlorodiiodide is produced. In aq. soln., S. W. Young and M. Adams found that a mixture of iodine and stannous chloride furnishes mixed crystals of stannous chloride and iodide. M. C. Schuyten said that when iodine or bromine are triturated with a soln. of stannous chloride, the halogen is greedily absorbed, the mixture becomes turbid, and finally clear. For the solubility of stannous chloride in **hydrochloric acid,** *vide supra.* A. Ditte observed no formation of a *stannous hydrochloride* when **hydrogen chloride** is passed

over crystals of hydrated stannous chloride. According to R. Engel, when hydrogen chloride is passed into a sat. aq. soln. of stannous chloride in water, a part of the salt is at first precipitated, but later on is dissolved. If the soln. sat. with hydrogen chloride at 0° is cooled to −40°, crystals of trihydrated **hydrotrichlorostannous acid**, $HSnCl_3$, are formed. The salt melts at −27° to −28°. This acid furnishes **trichlorostannites** of the type $MSnCl_3$. S. W. Young measured the electrical conductivity of soln. of stannous chloride in hydrochloric acid, and inferred that hydrotrichlorostannous acid, $HSnCl_3$, and **hydrotetrachlorostannous acid**, H_2SnCl_4, are formed. He also found that potassium chloride and potassium iodide have a marked tendency to form complexes with stannous chloride. J. C. G. de Marignac obtained a series of **tetrachlorostannites** ; and A. B. Poggiale reported a series of **hexachlorostannites,** but G. M. Richardson could not verify this result—*vide infra*. According to A. J. Balard, a soln. of stannous chloride reduces **hypochlorous acid** to chlorine. A. Naumann and co-workers found the oxidation of stannous chloride by a mixture of **potassium chlorate** is much accelerated by a trace of vanadic oxide. F. Jean showed that with **antimony pentachloride,** stannous chloride forms a mixture of stannic and antimonous chlorides.

If a soln. of stannous chloride be boiled with **sulphur,** G. Vortmann and C. Padberg found that half the tin is precipitated as stannous sulphide, and half remains in soln. as stannic chloride. If much free hydrochloric acid be present, all the tin is converted into stannic chloride, and hydrogen sulphide is evolved—*vide* sulphur—and E. Trautmann said that a hydrochloric acid soln. of stannous chloride acts on sulphur or **selenium,** forming respectively hydrogen sulphide or selenide. Stannous sulphide is precipitated when **hydrogen sulphide** is passed into a soln. of stannous chloride. E. Hering found that a soln. of stannous chloride becomes turbid when treated with **sulphur dioxide,** especially when heated, forming stannic chloride and sulphide : $6SnCl_2 + 2SO_2 + 8HCl = 5SnCl_4 + SnS_2 + 4H_2O$. M. M. P. Muir observed the separation of sulphur when a hot soln. of stannous chloride is treated with sulphur dioxide. R. G. Durrant found that the result of the action of sulphur dioxide on stannous chloride depends on the relative proportions of the components of the reaction. The primary reaction is $3SnCl_2 + 6HCl + H_2SO_3 = 3SnCl_4 + H_2S + 3H_2O$, and this is accompanied by the three consecutive reactions : $2H_2S + H_2SO_3 = 3H_2O + 3S$; $2H_2S + SnCl_4 = SnS_2 + 4HCl$; and $H_2S + SnCl_2 = SnS + 2HCl$. There is a slight reversion of the oxidation process : $SnCl_4 + H_2SO_3 + H_2O = SnCl_2 + 2HCl + H_2SO_4$. For complete oxidation, the stannous chloride, sulphur dioxide, and hydrochloric acid must be approximately in the proportions 3 : 1·55 : 6. The speed of the reaction in the presence of hydrochloric acid is bimolecular—*vide* sulphur dioxide. J. Girardin found that the dissolution of hydrated stannous chloride in hydrochloric acid containing a trace of sulphurous acid furnishes a yellow turbid liquid, which, when diluted with water, evolves a little hydrogen sulphide, and precipitates a brown mixture of stannic oxide and sulphide. N. S. von Fedoroff showed that sulphides of other metals—copper, arsenic, antimony, bismuth, and platinum—are formed when their salts are treated with hydrochloric acid soln. of stannous chloride and sulphur dioxide, while all the tin remains in soln. as stannic chloride. A. Vogel found that conc. **sulphuric acid** and a cold soln. of stannous chloride produce only a little hydrogen chloride, a little stannic sulphate, stannic chloride, sulphur dioxide, hydrogen sulphide, and free sulphur. R. G. Durrant said that the action of an excess of conc. sulphuric acid on hydrated stannic chloride takes place in three consecutive stages : (i) dehydration ; (ii) the liberation of hydrogen chloride between 20° and 90° ; and (iii) the liberation of sulphur dioxide between 130° and 200° with the formation of stannic sulphate : $SnSO_4 + 2H_2SO_4 = Sn(SO_4)_2 + 2H_2O + SO_2$. If water be present, a number of secondary reactions occur owing to the action of the sulphurous acid and the hydrogen chloride in soln. According to C. C. Persoz, a hot soln. of stannous chloride gives a precipitate of stannic sulphide when treated with **trithionic acid.**

The behaviour of **ammonia** towards aq. soln. of stannous chloride is indicated
